Agriculture

Encyclopedia of Agricultural, Food, and Biological Engineering, 2nd Ed., 2 Vols. K10554 (978-1-4398-1111-5)	Pub'd. 10/21/10 K11382 (978-1-4398-2806-9)
Encyclopedia of Animal Science, 2nd Ed., 2 Vols. K10463 (978-1-4398-0932-7)	Pub'd. 2/1/11 K10528 (978-0-415-80286-4)
Encyclopedia of Biotechnology in Agriculture and Food DK271X (978-0-8493-5027-6)	Pub'd. 7/16/10 DKE5044 (978-0-8493-5044-3)
Encyclopedia of Pest Management DK6323 (978-0-8247-0632-6)	Pub'd. 5/9/02 DKE517X (978-0-8247-0517-6)
Encyclopedia of Plant and Crop Science DK1190 (978-0-8247-0944-0)	Pub'd. 2/27/04 DKE9438 (978-0-8247-0943-3)
Encyclopedia of Soil Science, 3rd Ed., 3 Vols. K26612 (978-1-4987-3890-3)	Publishing 2016 K26614 (978-1-4987-3893-4)
Encyclopedia of Water Science, 2nd Ed., 2 Vols. DK9627 (978-0-8493-9627-4)	Pub'd. 12/26/07 DKE9619 (978-0-8493-9619-9)

Business and Computer Science

Encyclopedia of Computer Sci. & Tech., 2nd Ed., 2 Vols. K21573 (978-1-4822-0819-1)	Publishing 2016 K21578 (978-1-4822-0822-1)
Encyclopedia of Information Assurance, 4 Vols. AU6620 (978-1-4200-6620-3)	Pub'd. 12/21/10 AUE6620 (978-1-4200-6622-7)
Encyclopedia of Information Systems and Technology, 2 Vols. K15911 (978-1-4665-6077-2)	Pub'd. 12/29/15 K21745 (978-1-4822-1432-1)
Encyclopedia of Library and Information Sciences, 4th Ed. K15223 (978-1-4665-5259-3)	Publishing 2017 K15224 (978-1-4665-5260-9)
Encyclopedia of Software Engineering, 2 Vols. AU5977 (978-1-4200-5977-9)	Pub'd. 11/24/10 AUE5977 (978-1-4200-5978-6)
Encyclopedia of Supply Chain Management, 2 Vols. K12842 (978-1-4398-6148-6)	Pub'd. 12/21/11 K12843 (978-1-4398-6152-3)
Encyclopedia of U.S. Intelligence, 2 Vols. AU8957 (978-1-4200-8957-8)	Pub'd. 12/19/14 AUE8957 (978-1-4200-8958-5)
Encyclopedia of Wireless and Mobile Communications, 2nd Ed., 3 Vols. K14731 (978-1-4665-0956-6)	Pub'd. 12/18/12 KE16352 (978-1-4665-0969-6)

Chemistry, Materials and Chemical Engineering

Encyclopedia of Chemical Processing, 5 Vols. DK2243 (978-0-8247-5563-8)	Pub'd. 11/1/05 DKE499X (978-0-8247-5499-0)
Encyclopedia of Chromatography, 3rd Ed. 84593 (978-1-4200-8459-7)	Pub'd. 10/12/09 84836 (978-1-4200-8483-2)
Encyclopedia of Iron, Steel, and Their Alloys, 5 Vols. K14814 (978-1-4665-1104-0)	Pub'd. 1/6/16 K14815 (978-1-4665-1105-7)
Encyclopedia of Plasma Technology, 2 Vols. K14378 (978-1-4665-0059-4)	Publishing 2016 K21744 (978-1-4822-1431-4)
Encyclopedia of Supramolecular Chemistry, 2 Vols. DK056X (978-0-8247-5056-5)	Pub'd. 5/5/04 DKE7259 (978-0-8247-4725-1)
Encyclopedia of Surface & Colloid Science, 3rd Ed., 10 Vols. K20465 (978-1-4665-9045-8)	Pub'd. 8/27/15 K20478 (978-1-4665-9061-8)

Print	Online
-------	--------

Engineering

Dekker Encyclopedia of Nanoscience and Nanotechnology, 3rd Ed., 7 Vols. K14119 (978-1-4398-9134-6)	Pub'd. 3/20/14 K14120 (978-1-4398-9135-3)
Encyclopedia of Energy Engineering and Technology, 2nd Ed., 4 Vols. K14633 (978-1-4665-0673-2)	Pub'd. 12/1/14 KE16142 (978-1-4665-0674-9)
Encyclopedia of Optical and Photonic Engineering, 2nd Ed., 5 Vols. K12323 (978-1-4398-5097-8)	Pub'd. 9/22/15 K12325 (978-1-4398-5099-2)

Environment

Encyclopedia of Environmental Management, 4 Vols. K11434 (978-1-4398-2927-1)	Pub'd. 12/13/12 K11440 (978-1-4398-2933-2)
Encyclopedia of Environmental Science and Engineering, 6th Ed., 2 Vols. K10243 (978-1-4398-0442-1)	Pub'd. 6/25/12 KE0278 (978-1-4398-0517-6)
Encyclopedia of Natural Resources, 2 Vols. K12418 (978-1-4398-5258-3)	Pub'd. 7/23/14 K12420 (978-1-4398-5260-6)

Medicine

Encyclopedia of Biomaterials and Biomedical Engineering, 2nd Ed. H7802 (978-1-4200-7802-2)	Pub'd. 5/28/08 HE7803 (978-1-4200-7803-9)
Encyclopedia of Biomedical Polymers and Polymeric Biomaterials, 11 Vols. K14324 (978-1-4398-9879-6)	Pub'd. 4/2/15 K14404 (978-1-4665-0179-9)
Encyclopedia of Biopharmaceutical Statistics, 3rd Ed. H100102 (978-1-4398-2245-6)	Pub'd. 5/20/10 HE10326 (978-1-4398-2246-3)
Encyclopedia of Clinical Pharmacy DK7524 (978-0-8247-0752-1)	Pub'd. 11/14/02 DKE6080 (978-0-8247-0608-1)
Encyclopedia of Dietary Supplements, 2nd Ed. H100094 (978-1-4398-1928-9)	Pub'd. 6/25/10 HE10315 (978-1-4398-1929-6)
Encyclopedia of Medical Genomics and Proteomics, 2 Vols. DK2208 (978-0-8247-5564-5)	Pub'd. 12/29/04 DK501X (978-0-8247-5501-0)
Encyclopedia of Pharmaceutical Science and Technology, 4th Ed., 6 Vols. H100233 (978-1-84184-819-8)	Pub'd. 7/1/13 HE10420 (978-1-84184-820-4)

Routledge Encyclopedias

Encyclopedia of Public Administration and Public Policy, 3rd Ed., 5 Vols. K16418 (978-1-4665-6909-6)	Pub'd. 11/6/15 K16434 (978-1-4665-6936-2)
Routledge Encyclopedia of Modernism Y137844 (978-1-135-00035-6)	Pub'd. 5/11/16
Routledge Encyclopedia of Philosophy Online RU22334 (978-0-415-24909-6)	Pub'd. 11/1/00
Routledge Performance Archive Y148405 (978-0-203-77466-3)	Pub'd. 11/12/12

Brief Contents

Volume I

Accounting: Emergy Analysis	1	Arsenic: Southeast Asia	161
Acid Mine Drainage	6	Art and Soil	168
Acid Rain: Nitrogen Deposition	11	Atterberg Limits	171
Acid Sulfate Soils	17	Bacteria	175
Acid Sulfate Soils: Distribution and Extent	20	Biochar and Soil Characteristics	184
Acid Sulfate Soils: Formation	26	Biochar and Soil Quality	189
Acid Sulfate Soils: Management	31	Biochar: Soil Carbon and Fertility	193
Acid Sulfate Soils: Problems	36	Biodegradation and Bioremediation	198
Actinobacteria	40	Biodiversity and Sustainability	205
Aeration: Measurement	44	Bioenergy Crops: Carbon Balance Assessment	210
Aeration: Tillage Effects	47	Biofuels versus Agricultural Soils	213
Aggregates: Tensile Strength	51	Biological Crusts	216
Aggregation	55	Biological Nitrogen Fixation	220
Aggregation: Soil Organic Matter (SOM) and	58	Biological Nitrogen Fixation: Contributions to Agriculture	223
Aggregation: Structural Stability Measurement	61	Biological Nitrogen Fixation: Enhancement Techniques	227
Agricultural Lands: Flooding and Levee Breaches	65	Biological Nitrogen Fixation: Forms and Regulating Factors	232
Agricultural Management: Root Growth	72	Biota	235
Agricultural Soil Carbon: Trading	76	Biota and Disease-Suppressive Soils	239
Air Permeability	85	Biotechnology	243
Albedo	89	Boreal Forest	247
Alfisols	92	Boron and Molybdenum	252
Allophanes	97	Brick Making: Soil Degradation	255
Alpine Soils	101	Bulk Density	258
Aluminum	105	Bunch Planting: Water Conservation	261
Amazon Basin Soils	111	Calcification	264
Amendments and Ameliorants	114	Calcium	267
Ammonia: Volatilization from Agricultural Soils	117	Carbon Assessment: Spectroscopic Methods	270
Amoozometer	120	Carbon Sequestration: Fish Ponds	274
Anaerobic Processes	126	Carbon Sequestration: Geologic	279
Andisols	130	Carbon Sequestration: Iceland	284
Andisols: Iceland	134	Carbon Sequestration: Nutrient Management	288
Animals: Ecosystem Functioning	138	Carbon Sequestration: Sediments	294
Animals: Microbial Interactions and Nutrient Cycling	142	Carbon Sequestration: Semiarid Regions of India	299
Antimony	146	Carbon Sequestration: Urban Ecosystems	307
Ants	150	Carbon Sink Capacity: Soil Profile Characteristics	315
Archaeology	154	Carbon: Inelastic Neutron Scattering	319
Arid Soils	157	Carbon: Laser-Induced Breakdown Spectroscopy	323

Volume I (*cont'd.*)

Carbon: Physical Protection	327	Crop Evapotranspiration: Measurement System	488
Carbonates	331	Crop Management: Seasonally Frozen Soil	492
Carbonates: Secondary and Pedogenic	335	Crop Plants: Phosphorus Availability	494
Carbonates: Water and	339	Crop Residue Management	497
Care of Soil	342	Crop Root Response to Temperature: Temperate Zone	501
Cerrado	345	Crop Rotation and Farming Systems: Temperate Zone	504
Chemical Composition	348	Crop Rotation and Farming Systems: Tropical Smallholder Farm Systems	507
Chemisorption	353	Crop Rotation and Farming Systems: Tropics and Subtropics and Swelling Soils	512
Chernozems	356	Crop Yield: Compaction	516
Chlorine	362	Croplands	522
Classification Systems	367	Crops: Flooding Tolerance	526
Classification Systems: Arab Traditional, Moroccan Case	370	Cultivation: Raised-Bed	529
Classification Systems: Australian and New Zealand	375	Culture: Soil-less	533
Classification Systems: Brazilian	379	Cycling: Carbon and Nitrogen (C/N)	538
Classification Systems: Canadian	383	Debris Flow	544
Classification Systems: Chinese	389	Degradation	548
Classification Systems: French	391	Degradation: Biological	553
Classification Systems: Historical Developments	395	Degradation: Chemical	558
Classification Systems: Indian	398	Degradation: Critical Limits and Irreversible Degradation	561
Classification Systems: Indigenous	402	Degradation: Economic Incentives and Investments	565
Classification Systems: Major	406	Degradation: Farm-Level Economic Implications	568
Classification Systems: Netherlands	412	Degradation: Food Aid Needs in Low-Income Countries	571
Classification Systems: Russian	415	Degradation: Food Security and Poverty	574
Classification Systems: South African	418	Degradation: Greenhouse Effect	578
Clay Minerals	421	Degradation: Mapping by Normalized Difference Vegetation Index (NDVI)	581
Clay Minerals: Charge Properties	426	Degradation: Off-Farm Economic Implications	593
Clay Minerals: Weathering and Alteration of	430	Degradation: Physical	596
Climate	435	Degradation: Quality and	602
Climate Change: Gas Fluxes	438	Desertification: Biological Productivity Decline	608
Climate Change: Soil Carbon Sequestration	442	Desertification: Extent	616
Cobalt and Iodine	445	Desertification: Greenhouse Effect	620
Collembola	448	Desertification: Humid Environment in Iceland	623
Color	452	Desertification: Impact	628
Compaction	456	Desertification: Mapping Constraints and Challenges	633
Conditioning Index	459	Desertification: Prevention and Restoration	642
Conservation Tillage	462		
Conserved Lands: Stewardship	466		
Consistence	471		
Consolidation	474		
Controlled Traffic	477		
Copper	481		
Cover Crops	484		

Desertification: Productivity	645
Desertification: Restoration	648
Desertification: Reversal	654
Desertization: Irreversible Extension of Desert Land	657
Developing Countries: Economics of Soil Management	664
Diagnostic Horizons	668
Diffusivity: Measurement	672
Digital Soil Mapping	675
Drainage: Aeration and Trafficability	680
Drainage: Anaerobiosis	683
Drainage: Water Quality	689
Drought: Drought Resistance	693
Drought: Precipitation, Evapotranspiration, and Soil Moisture	698
Earthworms	701
Eco-Agriculture	706
Ecology: Cycling of Carbon and Nitrogen	711
Economics of Soil Management: U.S.	716
Ecosystems: Life Attributes and Environment	719
Enchytraeidae	723
Entisols	728
Environmentally Friendly Indigenous Technologies	732
Enzymes	737
Erosion	742
Erosion Management: Hill Soils	746
Erosion Tolerance	753
Erosion: Aggregate Breakdown Mechanisms	757
Erosion: Agronomic Practices	762
Erosion: Assessment	767
Erosion: Carbon Dioxide	777
Erosion: Controlling Irrigation-Induced	782
Erosion: Crop Yield	786
Erosion: Disturbed Lands	790
Erosion: Effects on Human Life	794
Erosion: Fly-Ash Spheres as Time Marker	798
Erosion: Global Change	804
Erosion: On-Site and Off-Site Impacts	811
Erosion: Overland Research and Measurement Techniques	814
Erosion: Perennial Crop Plantations	819
Erosion: Sedimentation Control Amendment Techniques	823
Erosion: Sedimentation Control Vegetative Techniques	827
Erosion: Snowmelt	831

Erosion: Soil Conservation	834
Erosion: Water Quality	838
Erosivity and Erodibility	845

Volume II

Ethics	848
Eutrophication	855
Evaporation	858
Evolution: Soil Seed Bank	868
Fauna	871
Fauna and Microflora: Macrofauna	877
Fertility Decline: Definitions and Assessment	880
Fertility: Environmentally Compatible Management	884
Fertility: Evaluation Systems	890
Fertility: Low Input and Traditional Maintenance Methods	894
Fertility: North China Plains	899
Fertilizers: Application Methods	903
Fertilizers: Leaching Losses	907
Fertilizers: Mineral	910
Fertilizers: Organic	916
Fertilizers: Types and Formulations	919
Fertilizers: Urban Waste and Sludges	923
Fire and Soils	926
Fluid Flow: Modeling	930
Food Crops: Zinc and Iron Biofortification	933
Food Security and Soil Water Management	939
Food Security: Agricultural Productivity and Resources	942
Food Security: Soil Degradation, Global Scale	945
Food Security: Soil Degradation, Local and Eco-Regional Scale	950
Forest Soils	955
Forest Soils: Calcium Depletion	959
Forest Soils: Major	963
Forest Soils: Nutrient Cycling	966
Forest Soils: Properties and Site Productivity	969
Freeze and Thaw: Diurnal	973
Frozen Soils: Water Relations	976
Fungi	979
Future of Soil Science	982
Gas and Vapor Phase Transport	986
Gelisols	989
Geologic Carbon Capture and Storage	992
Geology and Soil	997
Geomorphology	1000

Volume II (*cont'd.*)

Geophysical Methods	1004	Inorganic Carbon: Composition and Formation	1199
Geostatistics	1012	Inorganic Carbon: Global Carbon Cycle	1203
GIS Integration: Remote Sensing	1017	Inorganic Carbon: Global Stocks	1206
Global Resources	1020	Inorganic Carbon: Land Use Impacts	1210
Grass Strip Hydrology	1024	Inorganic Carbon: Modeling	1213
Grasslands Soils	1029	Insect Survival: Subzero Temperature	1217
Grazing Lands: Gaseous Emissions	1034	Integrated Nutrient Management	1221
Green Revolution: China North Eastern Plains	1042	Integrated Nutrient Management: Sustainability	1227
Greenhouse Effect	1048	International Soil Reference and Information Centre (ISRIC)	1232
Growing Media	1053	International Union of Soil Sciences	1237
Gulley Erosion	1059	Ion Exchange	1241
Gypsic Soils	1064	Iron Oxides	1245
Gypsic Soils: Gypsum Formation	1068	Irrigation	1250
Hard-Setting Soils	1072	Irrigation: Efficiency	1256
Health	1076	Irrigation: Erosion	1261
Heat and Water Movement	1079	Irrigation: Historical Perspective	1264
Heat Capacity	1083	Irrigation: Soil Salinity	1269
Heat Flux	1086	Jhum: Cultivation	1273
Heavy Metals	1089	Jhum: Shifting Agriculture	1281
History of Soil Science	1093	Land Capability Analysis	1285
History of Soil Science: 1927-2000	1098	Land Capability Classification	1288
History of Soil Science: Early to Mid-20 th Century	1103	Land Evaluation	1291
Histosols	1107	Land Forms	1294
Human Culture and Soils	1112	Land Husbandry	1297
Human Dimensions: Soil Sustainability	1115	Land Restoration	1304
Human Health and Soil	1118	Land Use: Historic	1308
Human Society and Soil	1123	Land Use: Land Cover	1313
Human Society and the Planet: Soil as a Heritage	1127	Land Use: Planning and Geographic Information System (GIS)	1318
Hydraulic Conductivity	1133	Landfill Sites: Revegetation	1322
Hydrologic Cycle	1137	Landscape	1327
Hydropedology	1140	Landscape: Classification	1331
Hydrophobic and Hydrophilic Compounds	1144	Landscape: Development and Erosion	1336
Hydrophobicity	1147	Landscape: Elements	1339
Inceptisols	1151	Landscape: Relationships	1344
India: Problems and Potentialities	1157	Landslide and Landcreep	1348
Indigenous Soil Management	1164	Law and Legal Issues	1352
Indo-Gangetic Plain: Agro-Ecological Regions	1168	Law and Legal Issues: Land as Property	1355
Industrial Waste	1178	Leaching and Illuviation	1358
Infiltration: Management	1183	Liming and Lime Materials	1362
Infiltration: Properties	1187	Loess	1365
Inorganic Carbon: Analysis	1191	Loess Plateau	1370
Inorganic Carbon: Climate and Time	1195	Low-Carbon Technology: Brazilian Semiarid Ecosystems	1377
		Lower Himalayas: Soil Management	1382

Macroporosity	1388	Nutrients: Deficiency and Toxicity Symptoms . .	1585
Magnesium	1392	Nutrients: Diffusion, Bioavailability, and	
Manganese: Brazilian Soils	1396	Plant Uptake	1588
Manure Management: Gaseous Emissions	1400	Nutrients: Interactions in Soil–Plant System . .	1594
Manure: Compost and Biosolids	1406	Nutrients: Water Interactions	1597
Mapping Soil Carbon	1409	Organic Agriculture	1600
Mapping Soil Carbon: Stocks in Turkey	1412	Organic Carbon: Assessment Methods	1604
Materials and Soils	1416	Organic Carbon: Sequestration Concepts	1609
Mediterranean Agriculture: Rainfed,		Organic Carbon: Subsoil Pools	1614
Nitrogen Use Efficiency	1421	Organic Farming: China	1618
Metal–Clay Interactions	1426	Organic Fertilization: Heavy Metal Uptake . . .	1621
Microbial Biomass: Measurement	1429	Organisms and Soil Food Webs	1624
Microbial Communities	1433	Organo-Mineral Relationships	1629
Micromorphology and Soil Quality	1439	Oxisols	1635
Micronutrients and Human Health	1443	Pampas, The	1638
Mine Soils: Measuring Geogenic Carbon	1449	Pantanal, The	1643
Mine Soils: Miscanthus Plantations	1458	Paramos Soils	1648
Mine Soils: Open Cut Mine Rehabilitation . . .	1462	Particle Density	1652
Mine Soils: Reclamation and Soil Carbon		Particle Packing	1654
Sequestration	1466	Particle Shape	1659
Minerals: Amorphous	1469	Particle Size	1661
Minerals: Primary	1473	Peatlands	1668
Minerals: Secondary	1476	Pedological Modeling	1674
Minerals: Solubility	1480	Pedometrics	1677
Minirhizotron	1484	Pedotransfer Functions	1682
Mites	1488	Permafrost: Soil Temperature and Special	
Modern Civilization and Soils	1491	Problems	1687
Mulch Farming	1495	Petrocalcic Horizons	1691
Mycorrhiza of Forest Ecosystems	1502	pH	1695
Mycorrhizae: Soil Quality	1505	Phosphorus	1700
Nanofertilizers	1511	Phosphorus: Manure and Diet Modification . .	1705
Natural Resources: Interaction with Soil	1516	Phosphorus: Plant Nutrition and	
Nematodes	1518	Microorganism Contribution	1708
Nematodes and Soil	1523	Phosphorus: Spatial Speciation in	
Nexus Approach: Resource Management for		Agricultural Soils	1712
Soil Productivity	1530	Phytoremediation	1717
Nitrate Leaching Index	1535	Plant Growth: Oxygen Diffusion Rate	1725
Nitrate Leaching Management	1538	Plant Nutrients	1728
Nitrogen and its Transformations	1541	Plant Nutrients: Intensity, Quantity, and	
Nitrogen Index	1545	Buffer Power	1731
Nitrogen-15: Utilization	1551	Plant Nutrients: Sufficiency and	
Nitrous Oxide Emissions: Agricultural Soils . .	1555	Requirements	1735
Nitrous Oxide Emissions: Paddy Soils	1559	Plastic Properties	1740
Nitrous Oxide Emissions: Sources, Sinks,		Plinthite and Petroplinthite	1743
and Strategies	1562	Podzols	1747
No Till	1566	Polar Regions, The	1753
Nutrient Management	1570	Pollution	1758
Nutrient Management: Fertility and	1576	Pollution: Industrial Waste	1762

Volume II (*cont'd.*)

Pollution: Non-Point Source	1765
Pollution: Organic and Inorganic	1768
Pollution: Persistent Organic	1771
Pollution: Point Source	1776

Volume III

Porosity: Pore Size Distribution	1782
Potassium	1786
Potassium: Dynamics and Mineralogy	1791
Potassium: Nutrition in Semi-Arid Tropics	1796
Power Plants: Carbon Dioxide Capture	1798
Precision Agriculture: Engineering Aspects	1804
Precision Agriculture: Fertilization	1808
Precision Agriculture: Nutrient Cycling	1811
Precision Agriculture: Remote Sensing	1815
Productivity: Natural and Anthropogenic Disturbances	1819
Protection: Policy of the European Union	1823
Protozoa	1828
Pyrite	1831
Pyrogenic Carbon	1834
Quality	1837
Quality Index: Soil	1841
Quality: Assessment by Interpolation Techniques	1844
Quality: Carbon and Nitrogen Gases	1848
Quality: Critical Limits and Standardization	1853
Quality: Erosion	1856
Quality: Indicators	1859
Quality: Productivity	1862
Quality: Soil and Water	1866
Radiometric Survey	1872
Radionuclides	1876
Raindrop Impact and Splash Erosion	1881
Rapid Soil Analysis: Diffuse Reflectance Spectroscopy	1886
Rare Earth Elements	1891
Redox Phenomena	1896
Rehabilitation: Indicators and Monitoring	1899
Religious Aspects of Soil–Human Relationships	1903

- J. Somasundaram** / *Indian Council of Agricultural Research, Indian Institute of Soil Science, Bhopal, India*
- Deborah A. Soukup** / *Geomatrix Consultants, Inc., Bakersfield, California, U.S.A.*

- Graham P. Sparling** / *Landcare Research, Hamilton, New Zealand*
- Gerd Sparovek** / *Luiz de Queiroz College of Agriculture (ESALQ) Piracicaba, University of Sao Paulo, Sao Paulo, Brazil*
- Kurt Spokas** / *U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), St. Paul, Minnesota, U.S.A.*
- Victor R. Squires** / *Adelaide University, Adelaide, South Australia, Australia*
- Rameshwar D. Srivastava** / *National Energy Technology Laboratory, Science Applications International Corporation, Pittsburgh, Pennsylvania, U.S.A.*
- Witold Stepniewski** / *Technical University of Lublin, Lublin, Poland*
- Larry D. Stetler** / *Department of Geology and Geological Engineering, South Dakota School of Mines and Technology, Rapid City, South Dakota, U.S.A.*
- B.A. Stewart** / *Department of Agricultural Sciences, West Texas A&M University, Canyon, Texas, U.S.A.*
- Michael Stocking** / *School of Developmental Studies, University of East Anglia, Norwich, U.K.*
- Mark H. Stolt** / *Department of Natural Resources Science, University of Rhode Island, Kingston, Rhode Island, U.S.A.*
- Daniel G. Strawn** / *University of Idaho, Moscow, Idaho, U.S.A.*
- Donald L. Suarez** / *U.S. Salinity Laboratory, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Riverside, California, U.S.A.*
- R.U. Suganthi** / *National Institute of Animal Nutrition and Physiology, Bangalore, India*
- Matthew O. Sullivan** / *Department of Food, Agricultural and Biological Engineering, Ohio State University, Columbus, Ohio, U.S.A.*
- Jaya N. Surya** / *Regional Centre Delhi, National Bureau of Soil Survey and Land Use Planning, Indian Council of Agricultural Research (ICAR), New Delhi, India*
- David Susko** / *Environmental Science, Department of Natural Sciences, University of Michigan at Dearborn, Dearborn, Michigan, U.S.A.*
- Alon Tal** / *Mitrani Department of Desert Ecology, Jacob Blaustein Institute for Desert Research, Ben Gurion University, Beer-Sheva, Israel*
- John P. Tandarich** / *Hey and Associates, Inc., Chicago, Illinois, U.S.A.*
- Jorge Tarchitzky** / *Department of Soil and Water Sciences, Faculty of Agricultural, Food and Environmental Quality Sciences, Hebrew University of Jerusalem, Rehovot, Israel*
- Charles Tarnocai** / *Agriculture and Agri-Food Canada, Ottawa, Ontario, Canada*
- Moses M. Tenywa** / *Department of Soil Science, University of Makerere, Kampala, Uganda*
- Malak M. Tfaily** / *Environmental Molecular Sciences Laboratory, Pacific Northwest National Laboratory, Richland, Washington, U.S.A.*
- Janice E. Thies** / *Department of Crop and Soil Sciences, Cornell University, Ithaca, New York, U.S.A.*
- D.P. Thoma** / *University of Minnesota, St. Paul, Minnesota, U.S.A.*
- Grant W. Thomas** / *University of Kentucky, Lexington, Kentucky, U.S.A.*
- Robin N. Thwaites** / *School of Natural Resource Sciences, Queensland University of Technology, Brisbane, Queensland, Australia*
- Gary L. Tibke** / *U.S. Department of Agriculture—Wind Erosion Research Unit (USDA-WERU), Kansas State University, Manhattan, Kansas, U.S.A.*
- D.R. Tilley** / *Department of Environmental Science and Technology, University of Maryland, College Park, Maryland, U.S.A.*
- Ralph W. Tiner** / *U.S. Fish and Wildlife Service (FWS), Hadley, Massachusetts, U.S.A.*

- Judy Tisdall** / *Department of Agricultural Sciences, LaTrobe University, Bundoora, Victoria, Australia*
- Nikola Tolic** / *Environmental Molecular Sciences Laboratory, Pacific Northwest National Laboratory, Richland, Washington, U.S.A.*
- David Tongway** / *Ecosystem Sciences, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Canberra, Australian Capital Territory, Australia*
- Cássio A. Tormena** / *Departamento de Agronomia, State University of Maringa, Maringa, Brazil*
- Dan Towery** / *Natural Resource Specialist, Conservation Technology Information Center, West Lafayette, Indiana, U.S.A.*
- Clinton C. Truman** / *Southeast Watershed Research Laboratory, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Tifton, Georgia, U.S.A.*
- Jeff N. Tullberg** / *Farm Mechanisation, CTF Solutions, Gatton, Queensland, Australia*
- Ronald F. Turco** / *Department of Agronomy, Purdue University, West Lafayette, Indiana, U.S.A.*
- Yuksel Tuzel** / *Department of Horticulture, Ege University, Bornova, Turkey*
- Goro Uehara** / *Department of Agronomy and Soil Science, University of Hawaii, Honolulu, Hawaii, U.S.A.*
- April L. Ulery** / *Agronomy and Horticulture, New Mexico State University, Las Cruces, New Mexico, U.S.A.*
- Paul W. Unger** / *Conservation and Production Research Laboratory, U.S. Department of Agriculture (USDA), Bushland, Texas, U.S.A.*
- Norman Uphoff** / *Cornell University, Ithaca, New York, U.S.A.*
- David A.N. Ussiri** / *Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.*
- Rowena A. Valmonte-Santos** / *Environment and Production Technology Division, International Food Policy Research Institute (IFPRI), Washington, District of Columbia, U.S.A.*
- Oswald Van Cleemput** / *Faculty of Agricultural and Applied Biological Sciences, University of Ghent, Ghent, Belgium*
- Harold M. van Es** / *Department of Crop and Soil Sciences, Cornell University, Ithaca, New York, U.S.A.*
- M.E.F. van Mensvoort** / *Laboratory of Soil Science and Geology, Wageningen University and Research Center, Wageningen, the Netherlands*
- R. Scott Van Pelt** / *Wind Erosion and Water Conservation Research Unit, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Big Spring, Texas, U.S.A.*
- Eric Van Ranst** / *Geology and Soil Science, Ghent University, Ghent, Belgium*
- Ken Van Rees** / *Department of Soil Science, University of Saskatchewan, Saskatoon, Saskatchewan, Canada*
- Jan van Schilfgaarde** / *U.S. Department of Agriculture (USDA), Fort Collins, Colorado, U.S.A.*
- George F. Vance** / *Department of Renewable Resources, University of Wyoming, Laramie, Wyoming, U.S.A.*
- Tara T. VanToai** / *Soil Drainage Research Unit, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Columbus, Ohio, U.S.A.*
- Mariappan Velayutham** / *National Bureau of Soil Survey and Land Use Planning, Nagpur, India*

- Dalmo A.N. Vieira** / *National Sedimentation Laboratory, Arkansas State University, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Jonesboro, Arkansas, U.S.A.*
- Raphael A. Viscarra Rossel** / *Bruce E. Butler Laboratory, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Canberra, Australian Capital Territory, Australia*
- Dale H. Vitt** / *Department of Plant Biology and Center for Ecology, Southern Illinois University, Carbondale, Illinois, U.S.A.*
- Joel T. Walker** / *Department of Food, Agricultural and Biological Engineering, Ohio State University, Columbus, Ohio, U.S.A.*
- Markus G. Walsh** / *World Agroforestry Centre (ICRAF), Kisumu, Kenya*
- Michelle Wander** / *Department of Natural Resources and Environmental Sciences, University of Illinois at Urbana-Champaign, Urbana, Illinois, U.S.A.*
- Dong Wang** / *Department of Soil, Water, and Climate, University of Minnesota, St. Paul, Minnesota, U.S.A.*
- Fanghao Wang** / *College of Resources and Environmental Sciences, China Agricultural University, Beijing, China*
- Xingxiang Wang** / *Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*
- R.H. Wanjari** / *Indian Institute of Soil Science, Bhopal, India*
- Owen P. Ward** / *Department of Biology, University of Waterloo, Waterloo, Ontario, Canada*
- Sam C. Ward** / *Bicton, Western Australia, Australia*
- Eric D. Warner** / *Environmental Resources Research Institute, Pennsylvania State University, University Park, Pennsylvania, U.S.A.*
- Andrew Warren** / *Department of Geography, University College London, London, U.K.*
- Glenn A. Weesies** / *National Soil Erosion Research Laboratory, U.S. Department of Agriculture—Natural Resources Conservation Service (USDA-NRCS), West Lafayette, Indiana, U.S.A.*
- Johannes Bernhard Wehr** / *School of Land, Crop and Food Sciences, University of Queensland, St. Lucia, Queensland, Australia*
- Walter W. Wenzel** / *Institute of Soil Research, University of Natural Resources and Applied Life Sciences, Vienna, Austria*
- Larry T. West** / *National Soil Survey Center, U.S. Department of Agriculture—Natural Resources Conservation Service (USDA-NRCS) (Retired), Fayetteville, Arkansas, U.S.A.*
- Ian White** / *Australian National University, Canberra, Australian Capital Territory, Australia*
- Walter G. Whitford** / *Jornada Experimental Range, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Las Cruces, New Mexico, U.S.A.*
- Dennis Wichelns** / *International Water Management Unit, Colombo, Sri Lanka*
- Penny E. Widdison** / *Department of Geography, University of Durham, Durham, U.K.*
- Keith D. Wiebe** / *Resource Economics Division, U.S. Department of Agriculture (USDA), Washington, District of Columbia, U.S.A.*
- Lucian Wielopolski** / *Environmental Sciences Department, Brookhaven National Laboratory, Upton, New York, U.S.A.*
- Giles F.S. Wiggs** / *Department of Geography, University of Sheffield, Sheffield, U.K.*
- Larry P. Wilding** / *Department of Soil and Crop Sciences, Texas A&M University, College Station, Texas, U.S.A.*
- Jimmy R. Williams** / *Texas A&M University, Temple, Texas, U.S.A.*

- Michael A. Wilson** / *U.S. Department of Agriculture—Natural Resources Conservation Service (USDA-NRCS), Lincoln, Nebraska, U.S.A.*
- Verena Winiwarter** / *Centre for Environmental History, Institute of Social Ecology, Interdisciplinary Research and Continuing Education (IFF), Vienna, Austria*
- William E. Wolfe** / *Department of Civil and Environmental Engineering and Geodetic Sciences, Ohio State University, Columbus, Ohio, U.S.A.*
- Ming H. Wong** / *Institute for Natural Resources and Land Management, Hong Kong Baptist University, Hong Kong, China*
- J.H.M. Wösten** / *Alterra Research Institute, Wageningen University and Research Center, Wageningen, the Netherlands*
- Graeme C. Wright** / *Department of Primary Industries, Queensland Department of Primary Industries, Kingaroy, Queensland, Australia*
- S.R. Wright** / *Ohio State University South Centers, Piketon, Ohio, U.S.A.*
- Chia Chun Joseph Wu** / *National Pingtung University of Science and Technology, Neipu, Taiwan*
- Pute Wu** / *Institute of Water Saving Agriculture in Arid Areas of China, Northwest A&F University, Yangling, China*
- Douglas Wysocki** / *Research Soil Scientist, National Soil Survey Center, Lincoln, Nebraska, U.S.A.*
- Guohua Xu** / *College of Resources and Environmental Sciences, Nanjing Agricultural University, Nanjing, China*
- Ren-kou Xu** / *State Key Laboratory of Soil and Sustainable Agriculture, Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*
- Ximeng Xu** / *Institute of Soil and Water Conservation, Northwest A&F University, Yangling, China*
- Jianfu Xue** / *College of Agronomy and Biotechnology, China Agricultural University, Beijing, China*
- Dan H. Yaalon** / *Institute of Earth Sciences, Hebrew University of Jerusalem, Jerusalem, Israel*
- R.P. Yadav** / *National Bureau of Soil Survey and Land Use Planning, Indian Council of Agricultural Research (ICAR), New Delhi, India*
- Ram Prashad Yadav** / *Regional Center, National Bureau of Soil Survey and Land Use Planning, New Delhi, India*
- Kazuyuki Yagi** / *National Institute for Agro-Environmental Sciences, Tsukuba, Japan*
- Laila Yesmin** / *Research and Development Division, Brett-Young Seeds Limited, Winnipeg, Manitoba, Canada*
- Dana D. York** / *Watershed and Landscape Programs Division, Natural Resources Conservation Service, U.S. Department of Agriculture (USDA-NRCS), Washington, District of Columbia, U.S.A.*
- Alper Yorulmaz** / *Department of Soil Science and Plant Nutrition, Adnan Menderes University, South Campus, Aydın, Turkey*
- Chin-Hsien Yu** / *Institute of Development Studies, Southwestern University of Finance and Economics, Chengdu, China*
- Don F. Yule** / *Department of Natural Resources, Rural Water Use Efficiency Initiative, Indooroopilly, Queensland, Australia*
- C. William Zanner** / *University of Nebraska, Lincoln, Nebraska, U.S.A.*
- Pandi Zdruli** / *Land and Water Resources Management Department, International Center for Advanced Mediterranean Agronomic Studies (CIHEAM) of Bari, Valenzano, Italy*

- Fusuo S. Zhang** / *College of Resources and Environmental Sciences, China Agricultural University, Beijing, China*
- Fusuo Zhang** / *College of Resources and Environmental Sciences, China Agricultural University, Beijing, China*
- Hailin Zhang** / *College of Agronomy and Biotechnology, China Agricultural University, Beijing, China*
- Jianhuan Zhang** / *Ohio State University, Columbus, Ohio, U.S.A.*
- Lulu Zhang** / *Institute for Integrated Management of Material Fluxes and of Resource, United Nations University, Dresden, Germany*
- Min Zhang** / *Chinese National Engineering Research Center for Slow/Controlled Release Fertilizers, Shandong Agricultural University, Taian, China*
- Taolin Zhang** / *Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China*
- X.-C. (John) Zhang** / *Grazinglands Research Laboratory, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), El Reno, Oklahoma, U.S.A.*
- Rui Zhao** / *Environmental Molecular Sciences Laboratory, Pacific Northwest National Laboratory, Richland, Washington, U.S.A.*
- Xin Zhao** / *College of Agronomy and Biotechnology, China Agricultural University, Beijing, China*
- Fenli Zheng** / *Institute of Soil and Water Conservation, Northwest A&F University, Yangling, China*
- Y.-G. Zhu** / *Research Centre for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing, China*
- Erik Zillmann** / *Institute of Plant Nutrition and Soil Science, Federal Agricultural Research Centre (FAL), Braunschweig, Germany*
- Yuri Lopes Zinn** / *Federal University of Lavras, Lavras, Brazil*
- Ted M. Zobeck** / *U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS) (Retired), Lubbock, Texas, U.S.A.*
- Michael A. Zoebisch** / *German Agency for International Cooperation, Tashkent, Uzbekistan*
- Yufeng Zou** / *Institute of Water Saving Agriculture in Arid Areas of China, Northwest A&F University, Yangling, China*
- Claudio Zucca** / *Integrated Water and Land Management (IWLMP) Research Program, International Center for Agricultural Research in the Dry Areas (ICARDA), Amman, Jordan*

Contents

<i>Editorial Advisory Board</i>	xiii
<i>Contributors</i>	xv
<i>Topical Table of Contents</i>	lxiii
<i>Preface</i>	lxxxiii
<i>About the Editors</i>	lxxxv

Volume I

Accounting: Emergy Analysis / Jay F. Martin and D.R. Tilley	1
Acid Mine Drainage / Jerry M. Bigham and Charles A. Cravotta III	6
Acid Rain: Nitrogen Deposition / George F. Vance	11
Acid Sulfate Soils / Delvin S. Fanning	17
Acid Sulfate Soils: Distribution and Extent / Wim Andriesse and M.E.F. van Mensvoort	20
Acid Sulfate Soils: Formation / Martin C. Rabenhorst, Delvin S. Fanning, and Steven N. Burch	26
Acid Sulfate Soils: Management / Michael D. Melville, Ian White, and Robert Quirk	31
Acid Sulfate Soils: Problems / Martin C. Rabenhorst and Delvin S. Fanning	36
Actinobacteria / Marketa Ságová-Marecková and Jan Kopecký	40
Aeration: Measurement / Robert E. Sojka and H.D. Scott	44
Aeration: Tillage Effects / Dave J. Horne and Robert E. Sojka	47
Aggregates: Tensile Strength / Humberto Blanco-Canqui and Rattan Lal	51
Aggregation / Sjoerd W. Duiker	55
Aggregation: Soil Organic Matter (SOM) and / Cynthia A. Cambardella	58
Aggregation: Structural Stability Measurement / Edmund Perfect, Martín Díaz-Zorita, and John Grove	61
Agricultural Lands: Flooding and Levee Breaches / Kenneth R. Olson and Lois Wright Morton	65
Agricultural Management: Root Growth / Susanne Schroetter, Jutta Rogasik, and Ewald Schnug	72
Agricultural Soil Carbon: Trading / Bruce A. McCarl, Sung Ju Cho, Jinxiu Ding, Pei Huang, Layla Shiva, and Chin-Hsien Yu	76
Air Permeability / Manoj K. Shukla and Rattan Lal	85
Albedo / Endre Dobos	89
Alfisols / Rienk Miedema	92
Allophanes / Leslie Louise Baker and Jodi Johnson-Maynard	97
Alpine Soils / Jérôme Poulenard and Pascal Podwojewski	101
Aluminum / Johannes Bernhard Wehr, Frederick Paxton Cardell Blamey, and Neal William Menzies	105
Amazon Basin Soils / Stanley W. Buol	111
Amendments and Ameliorants / David C. McKenzie	114
Ammonia: Volatilization from Agricultural Soils / Paul G. Saffigna and John R. Freney	117
Amoozemeter / Aziz Amoozegar	120
Anaerobic Processes / Paul A. McDaniel and Daniel G. Strawn	126
Andisols / Jon Chorover	130
Andisols: Iceland / Olafur Arnalds	134

Volume I (*cont'd.*)

Animals: Ecosystem Functioning / <i>Alan J. Franzluebbers</i>	138
Animals: Microbial Interactions and Nutrient Cycling / <i>Lisa Cole and Richard D. Bardgett</i>	142
Antimony / <i>Gudny Okkenhaug and Jan Mulder</i>	146
Ants / <i>Walter G. Whitford</i>	150
Archaeology / <i>John E. Foss</i>	154
Arid Soils / <i>H. Curtis Monger</i>	157
Arsenic: Southeast Asia / <i>Mohammad Mahmudur Rahman and Ravi Naidu</i>	161
Art and Soil / <i>Christian Feller</i>	168
Atterberg Limits / <i>Thomas Baumgartl</i>	171
Bacteria / <i>Mary Ann Bruns</i>	175
Biochar and Soil Characteristics / <i>Atanu Mukherjee and Rattan Lal</i>	184
Biochar and Soil Quality / <i>David A. Laird and Jeffrey M. Novak</i>	189
Biochar: Soil Carbon and Fertility / <i>Adam O'Toole and Daniel Rasse</i>	193
Biodegradation and Bioremediation / <i>Owen P. Ward and Ajay Singh</i>	198
Biodiversity and Sustainability / <i>Odo Primavesi</i>	205
Bioenergy Crops: Carbon Balance Assessment / <i>Rocky Lemus and Rattan Lal</i>	210
Biofuels versus Agricultural Soils / <i>David Pimentel</i>	213
Biological Crusts / <i>Jayne Belnap</i>	216
Biological Nitrogen Fixation / <i>Robert H. Burris</i>	220
Biological Nitrogen Fixation: Contributions to Agriculture / <i>Mark B. Peoples</i>	223
Biological Nitrogen Fixation: Enhancement Techniques / <i>David Francis Herridge</i>	227
Biological Nitrogen Fixation: Forms and Regulating Factors / <i>Ken E. Giller and Paul Mapfumo</i>	232
Biota / <i>Lev O. Karpachevsky and Mikhail Karpachevsky</i>	235
Biota and Disease-Suppressive Soils / <i>Nicola Lorenz</i>	239
Biotechnology / <i>Manas R. Banerjee and Laila Yesmin</i>	243
Boreal Forest / <i>Galina Mazhitova</i>	247
Boron and Molybdenum / <i>Umesh C. Gupta and J.A. MacLeod</i>	252
Brick Making: Soil Degradation / <i>G.S. Dheri, Babu S. Brar, and Debankur Sanyal</i>	255
Bulk Density / <i>Kwong Yin Chan</i>	258
Bunch Planting: Water Conservation / <i>B.A. Stewart</i>	261
Calcification / <i>Janis L. Boettinger</i>	264
Calcium / <i>Zdenko Rengel</i>	267
Carbon Assessment: Spectroscopic Methods / <i>James B. Reeves III and Gregory W. McCarty</i>	270
Carbon Sequestration: Fish Ponds / <i>Subhendu Adhikari and Rattan Lal</i>	274
Carbon Sequestration: Geologic / <i>Eswaran Padmanabhan</i>	279
Carbon Sequestration: Iceland / <i>Anna Maria Ágústsdóttir</i>	284
Carbon Sequestration: Nutrient Management / <i>M.C. Manna, Muneshwar Singh, R.H. Wanjari, Asit Mandal, and A.K. Patra</i>	288
Carbon Sequestration: Sediments / <i>Eswaran Padmanabhan</i>	294
Carbon Sequestration: Semiarid Regions of India / <i>Cherukumalli Srinivasa Rao, Sumanta Kundu, and Srinivas K.</i>	299
Carbon Sequestration: Urban Ecosystems / <i>Adam Louis Selhorst</i>	307
Carbon Sink Capacity: Soil Profile Characteristics / <i>Yuri Lopes Zinn</i>	315
Carbon: Inelastic Neutron Scattering / <i>Lucian Wielopolski</i>	319
Carbon: Laser-Induced Breakdown Spectroscopy / <i>Michael H. Ebinger, Ronny D. Harris, and Clifton W. Meyer</i>	323

Carbon: Physical Protection / Jennifer A.J. Dungait and David W. Hopkins	327
Carbonates / Douglas W. Ming	331
Carbonates: Secondary and Pedogenic / Ahmet R. Mermut and A. Landi	335
Carbonates: Water and / Michael Duniway	339
Care of Soil / Delia C. Catacutan	342
Cerrado / Igo F. Lepsch	345
Chemical Composition / Goro Uehara	348
Chemisorption / N.J. Barrow	353
Chernozems / Boris Boincean and Rattan Lal	356
Chlorine / Uzi Kafkafi and Guohua Xu	362
Classification Systems / Stephen Nortcliff	367
Classification Systems: Arab Traditional, Moroccan Case / Mohamed Sabir and Hassan Ben Jelloun	370
Classification Systems: Australian and New Zealand / Terry A. Isbell and A.E. Hewitt	375
Classification Systems: Brazilian / A.C.S. da Costa and M.R. Nanni	379
Classification Systems: Canadian / Charles Tarnocai	383
Classification Systems: Chinese / Zi-Tong Gong	389
Classification Systems: French / Jean-Paul Legros	391
Classification Systems: Historical Developments / Dan H. Yaalon	395
Classification Systems: Indian / Mariappan Velayutham, Tapas Bhattacharyya, and Dilip Kumar Pal	398
Classification Systems: Indigenous / Erhan Akça and Selim Kapur	402
Classification Systems: Major / Lars Krogh	406
Classification Systems: Netherlands / Alfred E. Hartemink and Henk de Bakker	412
Classification Systems: Russian / Maria Gerasimova	415
Classification Systems: South African / Jeffrey C. Hughes	418
Clay Minerals / C.D. Barton and Anastasios D. Karathanasis	421
Clay Minerals: Charge Properties / Christopher John Matocha	426
Clay Minerals: Weathering and Alteration of / Anastasios D. Karathanasis	430
Climate / Alexander N. Gennadiyev and Serge S. Chernyanskii	435
Climate Change: Gas Fluxes / Pascal Boeckx and Oswald Van Cleemput	438
Climate Change: Soil Carbon Sequestration / Sherwood E. Idso and Keith E. Idso	442
Cobalt and Iodine / Ronald G. McLaren	445
Collembola / Steve P. Hopkin	448
Color / Robin N. Thwaites	452
Compaction / William E. Wolfe	456
Conditioning Index / Ted M. Zobeck, M. Lee Norfleet, and Douglas L. Karlen	459
Conservation Tillage / Jack Cline and Robert Hendershot	462
Conserved Lands: Stewardship / Peter August, Janet Coit, and David Gregg	466
Consistence / Ray McBride	471
Consolidation / Tarunjit Singh Butalia	474
Controlled Traffic / Randall C. Reeder	477
Copper / Judith F. Pedler and David R. Parker	481
Cover Crops / Jorge A. Delgado, D. Wayne Reeves, and Ronald F. Follett	484
Crop Evapotranspiration: Measurement System / Huanjie Cai, Pute Wu, Zhijun Li, Xiaotao Hu, and Yufeng Zou	488
Crop Management: Seasonally Frozen Soil / Brenton S. Sharratt	492
Crop Plants: Phosphorus Availability / Bettina Eichler-Löbermann and Ewald Schnug	494

Volume I (*cont'd.*)

Crop Residue Management / <i>David L. Schertz and Dan Towery</i>	497
Crop Root Response to Temperature: Temperate Zone / <i>Thomas C. Kaspar</i>	501
Crop Rotation and Farming Systems: Temperate Zone / <i>Martin R. Carter</i>	504
Crop Rotation and Farming Systems: Tropical Smallholder Farm Systems / <i>Stefan Hauser, Lindsey Norgrove, and Tarcisius Nyobe</i>	507
Crop Rotation and Farming Systems: Tropics and Subtropics and Swelling Soils / <i>D.M. Freebairn, G.D. Smith, Robin D. Connolly, and Jeff N. Tullberg</i>	512
Crop Yield: Compaction / <i>Muhammad Ishaq and Rattan Lal</i>	516
Croplands / <i>B.A. Stewart</i>	522
Crops: Flooding Tolerance / <i>Tara T. VanToai, Getachew Boru, and Jianhuan Zhang</i>	526
Cultivation: Raised-Bed / <i>Kenneth D. Sayre</i>	529
Culture: Soil-less / <i>Nazim Gruda, Giorgio Prosdocimi Gianquinto, Yuksel Tuzel, and</i> <i>Dimitrios Savvas</i>	533
Cycling: Carbon and Nitrogen (C/N) / <i>Sylvie M. Brouder and Ronald F. Turco</i>	538
Debris Flow / <i>Jau-Yau Lu</i>	544
Degradation / <i>Rosa M. Poch Claret and José A. Martínez-Casasnovas</i>	548
Degradation: Biological / <i>Ibrahim Ortaş</i>	553
Degradation: Chemical / <i>M. Rifat Derici</i>	558
Degradation: Critical Limits and Irreversible Degradation / <i>Anthony R. Dexter and</i> <i>Michael A. Zoebisch</i>	561
Degradation: Economic Incentives and Investments / <i>Dennis Wichelns</i>	565
Degradation: Farm-Level Economic Implications / <i>Dennis Wichelns and Ellen Burnes</i>	568
Degradation: Food Aid Needs in Low-Income Countries / <i>Shahla Shapouri and Stacey Rosen</i>	571
Degradation: Food Security and Poverty / <i>Pierre Crosson</i>	574
Degradation: Greenhouse Effect / <i>Eddy De Pauw and Michael A. Zoebisch</i>	578
Degradation: Mapping by Normalized Difference Vegetation Index (NDVI) / <i>Zhanquo Bai</i> <i>and David Dent</i>	581
Degradation: Off-Farm Economic Implications / <i>Dennis Wichelns and Ellen Burnes</i>	593
Degradation: Physical / <i>Michael A. Zoebisch and Anthony R. Dexter</i>	596
Degradation: Quality and / <i>Rattan Lal</i>	602
Desertification: Biological Productivity Decline / <i>Uriel N. Safriel</i>	608
Desertification: Extent / <i>Victor R. Squires</i>	616
Desertification: Greenhouse Effect / <i>Craig Idso and Sherwood E. Idso</i>	620
Desertification: Humid Environment in Iceland / <i>Andres Arnalds</i>	623
Desertification: Impact / <i>David A. Mouat and Judith Lancaster</i>	628
Desertification: Mapping Constraints and Challenges / <i>Pandi Zdruli, Michael Cherlet, and</i> <i>Claudio Zucca</i>	633
Desertification: Prevention and Restoration / <i>Claudio Zucca, Susana Bautista, and</i> <i>Franco Previtali</i>	642
Desertification: Productivity / <i>Kris M. Havstad</i>	645
Desertification: Restoration / <i>Alon Tal</i>	648
Desertification: Reversal / <i>David Tongway and John Ludwig</i>	654
Desertization: Irreversible Extension of Desert Land / <i>Henry Noel LeHouérou</i>	657
Developing Countries: Economics of Soil Management / <i>Stefano Pagiola</i>	664
Diagnostic Horizons / <i>E.M. Bridges</i>	668
Diffusivity: Measurement / <i>Toru Nakajima</i>	672

Digital Soil Mapping / Budiman Minasny, Alex B. McBratney, and Florence Carré	675
Drainage: Aeration and Trafficability / Norman R. Fausey	680
Drainage: Anaerobiosis / Robert O. Evans	683
Drainage: Water Quality / James L. Baker	689
Drought: Drought Resistance / Graeme C. Wright and Nageswararao C. Rachaputi	693
Drought: Precipitation, Evapotranspiration, and Soil Moisture / Joshua B. Fisher and Konstantinos M. Andreadis	698
Earthworms / Patrick J. Bohlen	701
Eco-Agriculture / Norman Uphoff and Janice E. Thies	706
Ecology: Cycling of Carbon and Nitrogen / Alan J. Franzluebbers	711
Economics of Soil Management: U.S. / Jeffrey W. Hopkins	716
Ecosystems: Life Attributes and Environment / Dennis R. Linden	719
Enchytraeidae / María Jesús Iglesias Briones	723
Entisols / Larry T. West	728
Environmentally Friendly Indigenous Technologies / Selim Kapur and Erhan Akça	732
Enzymes / Veronica Acosta-Martinez and Susanne Klose	737
Erosion / Dennis C. Flanagan	742
Erosion Management: Hill Soils / Narendra Kumar Lenka and B. Krishna Rao	746
Erosion Tolerance / David L. Schertz and Mark A. Nearing	753
Erosion: Aggregate Breakdown Mechanisms / Yves Le Bissonnais	757
Erosion: Agronomic Practices / Glenn A. Weesies, David L. Schertz, and William F. Kuenstler	762
Erosion: Assessment / John Boardman	767
Erosion: Carbon Dioxide / Pierre A. Jacinthe and Rattan Lal	777
Erosion: Controlling Irrigation-Induced / Robert E. Sojka and David L. Bjorneberg	782
Erosion: Crop Yield / Michael Stocking	786
Erosion: Disturbed Lands / William J. Elliot	790
Erosion: Effects on Human Life / Neroli Pedro Cogo and Renato Levien	794
Erosion: Fly-Ash Spheres as Time Marker / Kenneth R. Olson and Alexander N. Gennadiyev	798
Erosion: Global Change / Xingxiang Wang, Taolin Zhang, Longxi Cao, and Yin Liang	804
Erosion: On-Site and Off-Site Impacts / Jerry L. Hatfield	811
Erosion: Overland Research and Measurement Techniques / Chia Chun Joseph Wu	814
Erosion: Perennial Crop Plantations / Alfred E. Hartemink	819
Erosion: Sedimentation Control Amendment Techniques / X.-C. (John) Zhang	823
Erosion: Sedimentation Control Vegetative Techniques / Samson D. Angima	827
Erosion: Snowmelt / Donald K. McCool	831
Erosion: Soil Conservation / Eric T. Craswell	834
Erosion: Water Quality / Andreas Klik	838
Erosivity and Erodibility / Peter I.A. Kinnell	845

Volume II

Ethics / John Ronald Engel	848
Eutrophication / Thomas G. Franti and Kyle D. Hoagland	855
Evaporation / William P. Kustas	858
Evolution: Soil Seed Bank / Paul B. Cavers and David Susko	868
Fauna / Mary C. Savin	871
Fauna and Microflora: Macrofauna / Judy Tisdall	877

Volume II (*cont'd.*)

Fertility Decline: Definitions and Assessment / Alfred E. Hartemink	880
Fertility: Environmentally Compatible Management / Bal Ram Singh	884
Fertility: Evaluation Systems / Ram C. Dalal and A. Subba Rao	890
Fertility: Low Input and Traditional Maintenance Methods / Miguel Altieri	894
Fertility: North China Plains / Xiangbin Kong and Rattan Lal	899
Fertilizers: Application Methods / John Ryan	903
Fertilizers: Leaching Losses / Paul G. Saffigna and Ian R. Phillips	907
Fertilizers: Mineral / L.L. Hammond and Balu L. Bumb	910
Fertilizers: Organic / Gary J. Gascho	916
Fertilizers: Types and Formulations / Douglas Robert McGuffog	919
Fertilizers: Urban Waste and Sludges / Rory O. Maguire and James Thomas Sims	923
Fire and Soils / Partap K. Khanna and John Raison	926
Fluid Flow: Modeling / John L. Nieber	930
Food Crops: Zinc and Iron Biofortification / Yashbir Singh Shivay and Rajendra Prasad	933
Food Security and Soil Water Management / Mark W. Rosegrant, Ephraim Nkonya, and Rowena A. Valmonte-Santos	939
Food Security: Agricultural Productivity and Resources / Keith D. Wiebe	942
Food Security: Soil Degradation, Global Scale / Michael A. Zebisch and Eddy De Pauw	945
Food Security: Soil Degradation, Local and Eco-Regional Scale / Sara J. Scherr	950
Forest Soils / Nicholas Comerford and Thomas Fox	955
Forest Soils: Calcium Depletion / Tom G. Huntington	959
Forest Soils: Major / Ken Van Rees	963
Forest Soils: Nutrient Cycling / Neil W. Foster and Jagtar S. Bhatti	966
Forest Soils: Properties and Site Productivity / Paul A. Arp and Helmut H. Krause	969
Freeze and Thaw: Diurnal / Joseph L. Pikul	973
Frozen Soils: Water Relations / John M. Baker	976
Fungi / Serita Frey	979
Future of Soil Science / Eric C. Brevik, Samuel J. Indorante, Dylan E. Beaudette, and Richard W. Arnold	982
Gas and Vapor Phase Transport / Dennis E. Rolston	986
Gelisols / James G. Bockheim	989
Geologic Carbon Capture and Storage / Sean I. Plasynski, John T. Litynski, Timothy R. Carr, Howard G. McIlvried, and Rameshwar D. Srivastava	992
Geology and Soil / Kenneth R. Olson	997
Geomorphology / Robin N. Thwaites	1000
Geophysical Methods / Barry J. Allred, Viacheslav I. Adamchuk, Raphael A. Viscarra Rossel, Jim Doolittle, Robert S. Freeland, Katherine R. Grote, and Dennis L. Corwin	1004
Geostatistics / Anja Gassner and Ewald Schnug	1012
GIS Integration: Remote Sensing / Egide Nizeyimana	1017
Global Resources / Paul Reich and Hari Eswaran	1020
Grass Strip Hydrology / Hossein Ghadiri and Calvin W. Rose	1024
Grasslands Soils / Douglas D. Malo	1029
Grazing Lands: Gaseous Emissions / Lipismita Samal, Veerasamy Sejian, M. Bagath, R.U. Suganthi, Raghavendra Bhatta, and Rattan Lal	1034
Green Revolution: China North Eastern Plains / Xiangbin Kong and Rattan Lal	1042
Greenhouse Effect / Rattan Lal	1048

Growing Media / Nazim Gruda, Jean Caron, Munoo Prasad, and Michael Maher	1053
Gulley Erosion / Fenli Zheng, Chihua Huang, and Ximeng Xu	1059
Gypsic Soils / Juan Herrero and Jaime Boixadera	1064
Gypsic Soils: Gypsum Formation / Ahmet R. Mermut and Hossein Khademi	1068
Hard-Setting Soils / Richard S.B. Greene	1072
Health / Robin F. Harris and D.E. Romig	1076
Heat and Water Movement / Gerald N. Flerchinger	1079
Heat Capacity / Surinder Kumar Jalota and B.S. Ghuman	1083
Heat Flux / Thomas J. Sauer	1086
Heavy Metals / Mike J. McLaughlin	1089
History of Soil Science / Eric C. Brevik and Artemi Cerdà	1093
History of Soil Science: 1927–2000 / Fred P. Miller	1098
History of Soil Science: Early to Mid-20th Century / John P. Tandarich	1103
Histosols / David L. Lindbo and Deborah A. Kozlowski	1107
Human Culture and Soils / Daniel Hillel	1112
Human Dimensions: Soil Sustainability / Mary Seely, Patrik Klintonberg, and Claus Hager	1115
Human Health and Soil / Charles F. Sing and David B. Sing	1118
Human Society and Soil / Rattan Lal	1123
Human Society and the Planet: Soil as a Heritage / Fred P. Miller	1127
Hydraulic Conductivity / Jacob H. Dane, Marc Jalbert, and Jan W. Hopmans	1133
Hydrologic Cycle / Keith R.J. Smettem	1137
Hydropedology / Henry Lin	1140
Hydrophobic and Hydrophilic Compounds / Tomas Simon	1144
Hydrophobicity / Joerg Bachmann, Abraham Marmur, and Markus Deurer	1147
Inceptisols / John M. Galbraith, Kenneth Scheffe, and Shawn McVey	1151
India: Problems and Potentialities / S.K. Singh, S. Chattaraj, N.G. Patil, S.K. Ray, and S. Chatterji	1157
Indigenous Soil Management / Karl Herweg	1164
Indo-Gangetic Plain: Agro-Ecological Regions / Jaya N. Surya, R.P. Yadav, G.S. Sidhu, and S.K. Singh	1168
Industrial Waste / Warren Dick	1178
Infiltration: Management / Jutta Rogasik, Kerstin Panten, Ewald Schnug, and Helmut Rogasik	1183
Infiltration: Properties / Walter J. Rawls	1187
Inorganic Carbon: Analysis / Richard R. Drees and C. Tom Hallmark	1191
Inorganic Carbon: Climate and Time / Lee C. Nordt	1195
Inorganic Carbon: Composition and Formation / H. Curtis Monger and Larry P. Wilding	1199
Inorganic Carbon: Global Carbon Cycle / William H. Schlesinger	1203
Inorganic Carbon: Global Stocks / Larry P. Wilding, Lee C. Nordt, and John M. Kimble	1206
Inorganic Carbon: Land Use Impacts / Donald L. Suarez	1210
Inorganic Carbon: Modeling / Leslie D. McFadden and Ronald G. Amundson	1213
Insect Survival: Subzero Temperature / Mike M. Ellsbury	1217
Integrated Nutrient Management / Bal Ram Singh and Ram C. Dalal	1221
Integrated Nutrient Management: Sustainability / G.S. Saroa and Rattan Lal	1227
International Soil Reference and Information Centre (ISRIC) / David Dent	1232
International Union of Soil Sciences / Stephen Nortcliff	1237
Ion Exchange / Bryon W. Bache	1241
Iron Oxides / Nikolla P. Qafoku and James Amonette	1245
Irrigation / Jack Keller	1250

Volume II (*cont'd.*)

Irrigation: Efficiency / Terry A. Howell	1256
Irrigation: Erosion / Robert E. Sojka and David L. Bjorneberg	1261
Irrigation: Historical Perspective / Robert E. Sojka, David L. Bjorneberg, and J.A. Entry	1264
Irrigation: Soil Salinity / James D. Rhoades	1269
Jhum: Cultivation / Arun Jyoti Nath, Biplab Brahma, Rattan Lal, and Ashesh Kumar Das	1273
Jhum: Shifting Agriculture / P.S. Ramakrishnan	1281
Land Capability Analysis / Michael J. Singer	1285
Land Capability Classification / Thomas E. Fenton	1288
Land Evaluation / J. Herbert Huddleston	1291
Land Forms / Carolyn G. Olson	1294
Land Husbandry / Francis Shaxson and Malcolm Douglas	1297
Land Restoration / Richard W. Bell	1304
Land Use: Historic / J. Douglas Helms, Hari Eswaran, and Paul Reich	1308
Land Use: Land Cover / Andrew K. Skidmore	1313
Land Use: Planning and Geographic Information System (GIS) / Egide Nizeyimana and Jacob Opadeyi	1318
Landfill Sites: Revegetation / Gilbert Yuk-sing Chan and Ming H. Wong	1322
Landscape / George Hall	1327
Landscape: Classification / Philip Schoeneberger	1331
Landscape: Development and Erosion / Jon Harbor	1336
Landscape: Elements / Douglas Wysocki and C. William Zanner	1339
Landscape: Relationships / Timothy A. Quine	1344
Landslide and Landcreep / Jau-Yau Lu and Hao-Jung Shieh	1348
Law and Legal Issues / Ian Hannam and Ben Boer	1352
Law and Legal Issues: Land as Property / Paul Martin and John Page	1355
Leaching and Illuviation / Lynn E. Moody	1358
Liming and Lime Materials / Mark K. Conyers	1362
Loess / Fred E. Rhoton and Helaine W. Markewich	1365
Loess Plateau / Fenli Zheng, Ximeng Xu, and Xiubin He	1370
Low-Carbon Technology: Brazilian Semiarid Ecosystems / Antonio Pereira Filho, Vanderlise Giongo, Tony Jarbas Ferreira Cunha, Jose Texeira Filho, Tayane de Lima Santos, and Luiz Fernando Carvalho Leite	1377
Lower Himalayas: Soil Management / Anup Das, Ramkrushna Gi, Badapmain Makdoh, Dibyendu Sarkar, Jayanta Layek, Sandip Mandal, and Rattan Lal	1382
Macroporosity / Daniel Gimenez and Daniel Hirmas	1388
Magnesium / N.S. Bolan, K. Arulmozhiselvan, and P. Paramasivam	1392
Manganese: Brazilian Soils / Diego Antonio França de Freitas, Nilton Curi, and Nestor Kämpf	1396
Manure Management: Gaseous Emissions / Veerasamy Sejian, Lipismita Samal, M. Bagath, R.U. Suganthi, Raghavendra Bhatta, and Rattan Lal	1400
Manure: Compost and Biosolids / Bahman Eghball and Kenneth A. Barbarick	1406
Mapping Soil Carbon / Budiman Minasny, Brendan Malone, and Alex B. McBratney	1409
Mapping Soil Carbon: Stocks in Turkey / Gönül Aydın, Mehmet Ali Çullu, Sabit Erşahin, Erhan Akça, Emrah Erdoğan, Levent Atatanır, Alper Yorulmaz, Ahmet Çilek, Merve Ersoy, Somayyeh Rezzaghi Miavaghi, Selim Kapur, and Rattan Lal	1412
Materials and Soils / Selim Kapur, Erhan Akça, and Takanori Nagano	1416

Mediterranean Agriculture: Rainfed, Nitrogen Use Efficiency / <i>Àngela D. Bosch Serra</i>	1421
Metal—Clay Interactions / <i>Dean Hesterberg</i>	1426
Microbial Biomass: Measurement / <i>K.R. Islam and S.R. Wright</i>	1429
Microbial Communities / <i>K.R. Islam and S.R. Wright</i>	1433
Micromorphology and Soil Quality / <i>Ahmet R. Mermut</i>	1439
Micronutrients and Human Health / <i>Ram Phal Narwal, R.S. Malik, S.K. Malhotra, and Bal Ram Singh</i>	1443
Mine Soils: Measuring Geogenic Carbon / <i>David A.N. Ussiri and Rattan Lal</i>	1449
Mine Soils: Miscanthus Plantations / <i>Jose G. Guzman and Rattan Lal</i>	1458
Mine Soils: Open Cut Mine Rehabilitation / <i>Douglas J. Dollhopf</i>	1462
Mine Soils: Reclamation and Soil Carbon Sequestration / <i>Vasant A. Akala and Rattan Lal</i>	1466
Minerals: Amorphous / <i>April L. Ulery</i>	1469
Minerals: Primary / <i>Nikolaos I. Barbayiannis and Vissarion Z. Keramidas</i>	1473
Minerals: Secondary / <i>Deborah A. Soukup</i>	1476
Minerals: Solubility / <i>Wayne P. Robarge</i>	1480
Minirhizotron / <i>Verónica Muñoz-Romero, Luis López-Bellido, F. Javier López-Bellido, and Rafael J. López-Bellido</i>	1484
Mites / <i>Hans Klompen</i>	1488
Modern Civilization and Soils / <i>Kenneth R. Olson</i>	1491
Mulch Farming / <i>Rattan Lal</i>	1495
Mycorrhiza of Forest Ecosystems / <i>Ian A. Dickie</i>	1502
Mycorrhizae: Soil Quality / <i>Ibrahim Ortas</i>	1505
Nanofertilizers / <i>Ruiqiang Liu and Rattan Lal</i>	1511
Natural Resources: Interaction with Soil / <i>Dennis J. Greenland</i>	1516
Nematodes / <i>Christien H. Ettema</i>	1518
Nematodes and Soil / <i>Wilfrida Decraemer</i>	1523
Nexus Approach: Resource Management for Soil Productivity / <i>Kai Schwärzel, Reza Ardakanian, Tamara Avellán, and Lulu Zhang</i>	1530
Nitrate Leaching Index / <i>Harold M. van Es and Jorge A. Delgado</i>	1535
Nitrate Leaching Management / <i>John J. Meisinger, Jorge A. Delgado, and Ashok Alva</i>	1538
Nitrogen and its Transformations / <i>Oswald Van Cleemput and Pascal Boeckx</i>	1541
Nitrogen Index / <i>Jorge A. Delgado</i>	1545
Nitrogen-15: Utilization / <i>Jorge Benitez-Vega, Luis López-Bellido, Ramón Redondo, and Rafael J. López-Bellido</i>	1551
Nitrous Oxide Emissions: Agricultural Soils / <i>John R. Freney</i>	1555
Nitrous Oxide Emissions: Paddy Soils / <i>Jianfu Xue, Xin Zhao, and Hailin Zhang</i>	1559
Nitrous Oxide Emissions: Sources, Sinks, and Strategies / <i>Katsu Minami</i>	1562
No Till / <i>Paul W. Unger</i>	1566
Nutrient Management / <i>Jorge A. Delgado</i>	1570
Nutrient Management: Fertility and / <i>John L. Havlin</i>	1576
Nutrients: Deficiency and Toxicity Symptoms / <i>Noel J. Grundon</i>	1585
Nutrients: Diffusion, Bioavailability, and Plant Uptake / <i>Niels Erik Nielsen</i>	1588
Nutrients: Interactions in Soil—Plant System / <i>Fusuo S. Zhang, J. Shen, and Y.-G. Zhu</i>	1594
Nutrients: Water Interactions / <i>Ardell D. Halvorson</i>	1597
Organic Agriculture / <i>Kathleen Delate</i>	1600
Organic Carbon: Assessment Methods / <i>K.R. Islam</i>	1604
Organic Carbon: Sequestration Concepts / <i>Kenneth R. Olson</i>	1609
Organic Carbon: Subsoil Pools / <i>Klaus Lorenz and Rattan Lal</i>	1614

Volume II (*cont'd.*)

Organic Farming: China / Yuxin Miao, Fusuo Zhang, and Fanghao Wang	1618
Organic Fertilization: Heavy Metal Uptake / Ewald Schnug, Alexandra Izosimova, and Renata Gaj	1621
Organisms and Soil Food Webs / David C. Coleman	1624
Organo-Mineral Relationships / Claire Chenu, Alain F. Plante, and Pascale Puget	1629
Oxisols / Stanley W. Buol	1635
Pampas, The / Martín Díaz-Zorita and Daniel E. Buschiazso	1638
Pantanal, The / Henrique de Oliveira, Amaury de Carvalho Filho, Carlos Ernesto Reynauld G. Schaefer, and Evaldo Luis Cardoso	1643
Paramos Soils / Pascal Podwojewski and Jérôme Poulenard	1648
Particle Density / Keith R.J. Smettem	1652
Particle Packing / Satish C. Gupta and D.P. Thoma	1654
Particle Shape / Brian M. Schafer	1659
Particle Size / Hwat Bing So and Harold R. Geering	1661
Peatlands / Dale H. Vitt and Paul Short	1668
Pedological Modeling / Ronald G. Amundson	1674
Pedometrics / Alex B. McBratney and Budiman Minasny	1677
Pedotransfer Functions / J.H.M. Wösten	1682
Permafrost: Soil Temperature and Special Problems / Douglas Kane and Julia Boike	1687
Petrocalcic Horizons / Alain Ruellan	1691
pH / Grant W. Thomas	1695
Phosphorus / John Ryan and Abdul Rashid	1700
Phosphorus: Manure and Diet Modification / Rory O. Maguire, John T. Brake, and Peter W. Plumstead	1705
Phosphorus: Plant Nutrition and Microorganism Contribution / Bettina Eichler-Löbermann, Christel Baum, Silke Ruppel, and Ewald Schnug	1708
Phosphorus: Spatial Speciation in Agricultural Soils / Anja Gassner and Ewald Schnug	1712
Phytoremediation / Khan Towhid Osman and Md. Abul Kashem	1717
Plant Growth: Oxygen Diffusion Rate / Witold Stepniewski	1725
Plant Nutrients / Volker Roemheld	1728
Plant Nutrients: Intensity, Quantity, and Buffer Power / Ram C. Dalal	1731
Plant Nutrients: Sufficiency and Requirements / Kanwar L. Sahrawat	1735
Plastic Properties / Gunnar Kirchhof	1740
Plinthite and Petroplinthite / Eswaran Padmanabhan and Hari Eswaran	1743
Podzols / Peter Buurman	1747
Polar Regions, The / Charles Tarnocai and Iain Campbell	1753
Pollution / Zulkuf Kaya	1758
Pollution: Industrial Waste / Winfried E.H. Blum, Walter W. Wenzel, Wolfgang Friesl-Hanl, and Martin H. Gerzabek	1762
Pollution: Non-Point Source / Ravendra Naidu, Mallavarapu Megharaj, Peter Dillon, Rai Kookana, Ray Correll, and Walter W. Wenzel	1765
Pollution: Organic and Inorganic / A. Paul Schwab	1768
Pollution: Persistent Organic / Mark Radosevich and E. Danielle Rhine	1771
Pollution: Point Source / Ravendra Naidu, Mallavarapu Megharaj, Peter Dillon, Rai Kookana, Ray Correll, and Walter W. Wenzel	1776

Volume III

Porosity: Pore Size Distribution / Keith C. Cameron and Graeme D. Buchan	1782
Potassium / Philippe Hinsinger	1786
Potassium: Dynamics and Mineralogy / A.V. Shanwal and S.S. Dahiya	1791
Potassium: Nutrition in Semi-Arid Tropics / D.L. Oswalt	1796
Power Plants: Carbon Dioxide Capture / Sean I. Plasynski, Thomas J. Feeley, Timothy Fout, Howard G. McIlvried, and Rameshwar D. Srivastava	1798
Precision Agriculture: Engineering Aspects / Joel T. Walker, Reza Ehsani, and Matthew O. Sullivan ...	1804
Precision Agriculture: Fertilization / Silvia H. Haneklaus and Ewald Schnug	1808
Precision Agriculture: Nutrient Cycling / Robert J. Lascano	1811
Precision Agriculture: Remote Sensing / Kerstin Panten, Holger Lilienthal, Erik Zillmann, Silvia H. Haneklaus, and Ewald Schnug	1815
Productivity: Natural and Anthropogenic Disturbances / Douglas G. Maynard and Charlotte E. Norris	1819
Protection: Policy of the European Union / Irene L. Heuser and Luca Montanarella	1823
Protozoa / Bryan S. Griffiths	1828
Pyrite / Michael J. Borda	1831
Pyrogenic Carbon / Barry G. Rawlins	1834
Quality / Ed G. Gregorich	1837
Quality Index: Soil / Toru Nakajima	1841
Quality: Assessment by Interpolation Techniques / Vincent Obade	1844
Quality: Carbon and Nitrogen Gases / Philippe Rochette, Reynald Lemke, and Sean McGinn ...	1848
Quality: Critical Limits and Standardization / Martin R. Carter	1853
Quality: Erosion / Craig Ditzler	1856
Quality: Indicators / Graham P. Sparling	1859
Quality: Productivity / Mike H. Beare	1862
Quality: Soil and Water / Todd Nissen and Michelle Wander	1866
Radiometric Survey / Barry G. Rawlins and Raphael A. Viscarra Rossel	1872
Radionuclides / Philip M. Jardine	1876
Raindrop Impact and Splash Erosion / Hossein Ghadiri	1881
Rapid Soil Analysis: Diffuse Reflectance Spectroscopy / Keith D. Shepherd and Markus G. Walsh	1886
Rare Earth Elements / Zhengyi Hu, Gerd Sparovek, Silvia H. Haneklaus, and Ewald Schnug	1891
Redox Phenomena / Bruce R. James	1896
Rehabilitation: Indicators and Monitoring / David Jasper	1899
Religious Aspects of Soil—Human Relationships / Verena Winiwarter and Winfried E.H. Blum ...	1903
Rendzina / Thomas E. Fenton	1907
Resilience / Moses M. Tenywa, J.G.M. Majaliwa, and A. Lufafa	1909
Resilience: Land Use and Soil Management / Soojin J. Park	1913
Resilience: Quality and / Rattan Lal	1918
Resilience: Restoration / F.W.T. Penning de Vries and Eric T. Craswell	1924
Respiration / Pierre A. Jacinthe and Rattan Lal	1928
Restoration Ecology / Richard Hobbs	1932
Restoration: Success and Completion Criteria / Sam C. Ward	1935
Rice Paddies: Methane Emissions / Ronald L. Sass	1940
Rice Paddies: Methane Emissions, Mitigating / Kazuyuki Yagi	1943

Volume III (*cont'd.*)

Rice Paddies: Methanogenesis / Ronald L. Sass	1947
Rice Paddies: Soil Management / Xin Zhao, Jianfu Xue, and Hailin Zhang	1950
Rocks / Vsevolod V. Dobrovolsky	1953
Root Growth: Pressure at the Soil—Root Interface / Rabi K. Misra	1957
Root Monitoring System / Zhikuan Jia, Pute Wu, Qingfang Han, Junfeng Nie, Ruixia Ding, and Yufeng Zou	1960
Salt-Affected Soils / Anna Eynard, Rattan Lal, and Keith D. Wiebe	1965
Salt-Affected Soils: Nitrous Oxide Emissions / G.S. Dheri, Babu S. Brar, and Debankur Sanyal	1969
Satellite Mapping / Bruce E. Frazier	1972
Scaling Effects / Yakov A. Pachepsky, Walter J. Rawls, and John W. Crawford	1976
Sediment: Influence on Aquatic Life / Suzanne M. Gray	1981
Sedimentation Control and Erosion: Engineering Techniques / Jose Miguel Reichert and Elemar Antonino Cassol	1986
Seepage / Patricia M. Gallagher	1990
Selenium / Gunnar Gissel-Nielsen	1995
Serpentinitic Soils / Rebecca Burt and Michael A. Wilson	1999
Sesquioxides / Joey N. Shaw and Larry T. West	2003
Shrinkage / Des McGarry and Don F. Yule	2008
Silica: Pedogenic Accumulation / Katherine J. Kendrick	2012
Silicon and Sodium / Jian Feng Ma	2015
Slaking, Dispersion, and Crust Formation / Hwat Bing So	2021
Social and Behavioral Sciences' Contribution to Soil Science / Sven B. Lundstedt	2026
Sodic Soils / Pichu Rengasamy	2029
Sodic Soils: Formation and Global Distribution / Brian Murphy	2032
Sodic Soils: Humid Regions / Samuel J. Indorante	2037
Sodic Soils: Irrigation Farming / David Burrow	2041
Sodic Soils: Physical Properties and Behavior / Hwat Bing So	2044
Sodic Soils: Processes, Characteristics, and Classification / Pichu Rengasamy	2048
Sodic Soils: Reclamation / Jock Churchman	2051
Sodicity: Subsoil / Kwong Yin Chan	2056
Soil Carbon Map: Africa / Arwyn Jones, Roland Hiederer, and Luca Montanarella	2059
Soil Carbon Sequestration: Ethiopia / Ambachew Demessie, Bal Ram Singh, and Rattan Lal	2066
Soil Carbon: Compositional and Isotopic Analysis / James Moran, M. Lizabeth Alexander, and Alexander Laskin	2073
Soil Carbon: Farming and Economic Aspects / Bruce A. McCarl	2078
Soil Conservation: Incentives / David Sanders	2081
Soil Conservation: Strategies / Winfried E.H. Blum	2084
Soil Conservation: U.S. Historical Perspective / Dana D. York	2086
Soil Degradation: Global Assessment / Selim Kapur and Erhan Akça	2090
Soil Enzymes / Cherukumalli Srinivasa Rao, Minakshi Grover, Sumanta Kundu, and Susheelendra Desai	2100
Soil Organic Matter (SOM) / Rattan Lal	2108
Soil Organic Matter (SOM): Accumulation / Sylvie A. Quideau	2112
Soil Organic Matter (SOM): Available Water Capacity / Tom G. Huntington	2117

Soil Organic Matter (SOM): Characterization / Christian Feller	2123
Soil Organic Matter (SOM): Composition and Dynamics / Cornelia Rumpel, M.F. Dignac, and Abad Chabbi	2126
Soil Organic Matter (SOM): Global Carbon Cycle / Keith Paustian	2129
Soil Organic Matter (SOM): Global Distribution / Wilfred M. Post	2133
Soil Organic Matter (SOM): Historical Concepts / Christian Feller	2139
Soil Organic Matter (SOM): Landscape / Henry H. Janzen, B.H. Ellert, and D.W. Anderson	2142
Soil Organic Matter (SOM): Management / R. Cesar Izaurralde and Carlos C. Cerri	2147
Soil Organic Matter (SOM): Mass Spectrometry Data Analysis / Nikola Tolic, Malak M. Tfaily, Yufeng Shen, Rosalie Chu, Thomas Fillmore, Rui Zhao, Kent Bloodsworth, Errol Robinson, Ljiljana Paša-Tolić, and Nancy J. Hess	2154
Soil Organic Matter (SOM): Modeling / Peter Smith	2159
Soil Organic Matter (SOM): Molecular Simulations / Amity Andersen	2166
Soil Organic Matter (SOM): Nutrient Dynamics / Charles W. Rice	2172
Soil Organic Matter (SOM): Solvent-Based High Resolution Mass Spectrometry / Malak M. Tfaily, Yufeng Shen, Nikola Tolic, Jennifer Kyle, Rosalie Chu, Thomas Fillmore, Rui Zhao, Kent Bloodsworth, Errol Robinson, Ljiljana Paša-Tolić, and Nancy J. Hess	2176
Soil Organic Matter (SOM): Structure and Characterization / Georg Guggenberger	2180
Soil Organic Matter (SOM): Turnover / Johan Six and Julie D. Jastrow	2186
Soluble Salts: Translocation and Accumulation / Jimmie L. Richardson	2192
Solute Transport / Arne E. Olsen and James W. Jawitz	2194
Spectral Mixtures: Soil—Plant / Alfredo R. Huete	2197
Spodosols / Delbert Mokma	2200
Strontium / Silvia H. Haneklaus and Ewald Schnug	2203
Structure / Eileen J. Klodivko	2207
Structure: Belowground Management / Ken A. Olsson and Bruce Cockcroft	2209
Structure: Earthworms / Martin Shipitalo and Tayfun Korucu	2212
Structure: Pedological Concepts and Water Flow / Clinton C. Truman and Donald P. Franzmeier	2216
Structure: Plant Establishment / Douglas L. Karlen	2221
Structure: Roots / Alvin J.M. Smucker	2225
Sub-Irrigation / Norman R. Fausey	2228
Sugarcane Fields: Harvest Systems and Residue Management / Newton La Scala Jr., Ricardo De Oliveira Bordonal, Eduardo Barretto De Figueiredo, Alan Rodrigo Panosso, Mara Regina Moitinho, and Mariana Marotti Corradi	2231
Sulfate and Sulfide Minerals / Delvin S. Fanning and Steven N. Burch	2238
Sulfur / Ewald Schnug, Silvia H. Haneklaus, and Elke Bloem	2241
Sulfur: Chemical Behavior in the Rhizosphere / Zhengyi Hu, Silvia H. Haneklaus, and Ewald Schnug	2247
Sulfur: Nutrition / Silvia H. Haneklaus, Elke Bloem, and Ewald Schnug	2251
Surface Area: Specific / L.A. Graham Aylmore	2255
Surface Management / Kwong Yin Chan	2259
Surface Water: Nitrogen Enrichment / Tim P. Burt and Penny E. Widdison	2263
Surface Water: Pollution by Nitrogen Fertilizers / Gregory McIsaac	2268
Sustainable Agriculture: Social Aspects / Frederick H. Buttel	2273
Sustainable Agriculture: Soil Quality / John W. Doran and Ed G. Gregorich	2276
Sustainable Development and Sustainability / Alan D. Hecht and Joseph Fiksel	2280
Tailings: Minerals Processing Residue Rehabilitation / Lloyd R. Hossner and Hamid Shahandeh	2286

Volume III (*cont'd.*)

Taxonomies: U.S. Soil Taxonomy and Indian Scenario / <i>Tapas Bhattacharyya and Dilip Kumar Pal</i>	2291
Taxonomy / <i>Mark H. Stolt</i>	2295
Temperature Measurement / <i>Kevin McInnes</i>	2302
Tepetates: Mexico / <i>Jorge D. Etchevers, Claudia Hidalgo, C. Prat, and P. Quantin</i>	2305
Termites / <i>David E. Bignell and John A. Holt</i>	2309
Terra Preta (Black Earths) / <i>Kurt Spokas, Jose Marques Jr., Newton La Scala Jr., Ed Nater, and Diego S. Siqueira</i>	2312
Terra Preta de Indio / <i>Johannes Lehmann</i>	2316
Testing / <i>Yash P. Kalra and Jagtar S. Bhatti</i>	2320
Texture / <i>Harold R. Geering and Hwat Bing So</i>	2323
Tillage Erosion: Description and Process / <i>Michael J. Lindstrom</i>	2330
Tillage Erosion: Measurement Techniques / <i>David A. Lobb</i>	2333
Tillage Erosion: Properties and Productivity Effects / <i>Tom E. Schumacher</i>	2336
Tillage Erosion: Relationship to Water Erosion / <i>Gerard Govers</i>	2339
Tillage Erosion: Terrace Formation / <i>Seth M. Dabney and Dalmo A.N. Vieira</i>	2342
Tillage: Gas Exchange / <i>Donald C. Reicosky</i>	2348
Tilth / <i>Jerry L. Hatfield</i>	2351
Time and Space: Soils in / <i>Neil E. Smeck and C. Lee Burras</i>	2353
Torrential Erosion: Himalayas / <i>Ram Prashad Yadav</i>	2358
Trace Metal Contamination / <i>Åsgeir Rossebø Almås and Bal Ram Singh</i>	2364
Tropics and Subtropics / <i>Hari Eswaran and Eswaran Padmanabhan</i>	2369
Turbations / <i>Brad D. Lee and Robert C. Graham</i>	2373
Turfgrass: Protection of Soil and Water / <i>James A. Murphy and Stephanie L. Murphy</i>	2377
Ultisols / <i>Joey N. Shaw</i>	2380
Uranium Contamination / <i>Ewald Schnug, Roberta Bottino Montolar Sparovek, Maria del Carmen Lamas, Sylvia L. Kratz, Jurgen Fleckenstein, and Susanne Schroetter</i>	2385
Urban Lands: Abandoned / <i>Joshua W. Beniston and William D. Shuster</i>	2388
Urban Lands: and Construction Sites / <i>Wolfgang Burghardt</i>	2395
Urban Lands: Management / <i>Klaus Lorenz</i>	2400
Urban Wastewater for Irrigation: Heavy Metals / <i>P.S. Minhas and K. Lal</i>	2407
Urea: Subsoiling and Controlled Release / <i>Tangyuan Ning, Rattan Lal, Zengjia Li, and Min Zhang</i>	2411
Value of Soil to Humans / <i>Rattan Lal</i>	2416
Variability / <i>Josef H. Görres</i>	2419
Variability: Spatial / <i>Brian Slater</i>	2428
Variable Charge Soils: Mineralogy and Chemistry / <i>Eric Van Ranst, Nikolla P. Qafoku, Andrew Noble, and Ren-kou Xu</i>	2432
Vertisols / <i>Wouter A. Blokhuis</i>	2440
Vertisols: Surface Crack Management / <i>J. Somasundaram, Nishant K. Sinha, Ashok K. Patra, and Rattan Lal</i>	2450
Vesicular Crusts / <i>Patrick Drohan</i>	2456
Village Bamboos / <i>Arun Jyoti Nath, Ashesh Kumar Das, and Rattan Lal</i>	2459
Waste Rock and Overburden Dumps: Rehabilitation / <i>Martin V. Fey, R.D. O'Brien, and A.J. Mills</i>	2464
Wastewater: Treatment and Utilization in Irrigation / <i>Yona Chen and Jorge Tarchitzky</i>	2467

Water Conservation / <i>Paul W. Unger</i>	2472
Water Content / <i>Tom J. Jackson</i>	2475
Water Content: Passive and Active Microwave Remote Sensing / <i>Eric D. Warner and Gary W. Petersen</i>	2480
Water Erosion / <i>David Favis-Mortlock</i>	2485
Water Erosion: Empirical Models / <i>John M. Laflen</i>	2489
Water Erosion: Hybrid Models / <i>Jeffrey G. Arnold, Kevin W. King, and Jimmy R. Williams</i>	2494
Water Erosion: Modeling / <i>Calvin W. Rose</i>	2499
Water Erosion: Process-Based Modeling / <i>Mark A. Nearing</i>	2504
Water Infiltration / <i>Manoj K. Shukla and Rattan Lal</i>	2507
Water Management: Computer Modeling / <i>Laj R. Ahuja and Liwang Ma</i>	2510
Water Management: Harvesting / <i>Gary W. Frasier</i>	2515
Water Management: Use Efficiency / <i>David C. Nielsen</i>	2518
Water Measurement: Methods / <i>Des McGarry</i>	2522
Water Range: Least-Limiting / <i>Alvaro Pires da Silva, Beverly D. Kay, Cássio A. Tormena, Silvia Imhoff, Douglas L. Karlen, and Joseph G. Benjamin</i>	2530
Water Retention / <i>Satish C. Gupta and Dong Wang</i>	2535
Water: Plant-Available / <i>Argyrios Gerakis and Joe T. Ritchie</i>	2541
Water-Repellent Soils / <i>Anna Eynard, Rattan Lal, and Keith D. Wiebe</i>	2546
Watershed Approach / <i>Timothy R. Green and Jan van Schilfgaarde</i>	2550
Watershed Management: Remote Sensing and GIS Applications / <i>A.V. Shanwal and S.P. Singh</i>	2555
Weathering / <i>Dominique Righi</i>	2559
Weathering: Carbon Sequestration / <i>William Berry Lyons, Jerry M. Bigham, Anne E. Carey, and Rattan Lal</i>	2563
Wetlands / <i>Ralph W. Tiner</i>	2567
Wetlands: Biodiversity / <i>Jean-Claude Lefeuvre and Virginie Bouchard</i>	2572
Wetlands: Carbon Sequestration / <i>Virginie Bouchard and Matthew Cochran</i>	2576
Wetlands: Conservation Policy / <i>Clayton Rubec</i>	2580
Wetlands: Economic Value / <i>Gayatri Acharya</i>	2584
Wetlands: Gaseous Emissions / <i>S.K. Nag</i>	2589
Wetlands: Methane Emission / <i>Anna Ekberg and Torben Røjle Christensen</i>	2596
Wetlands: Sedimentation and Ecological Engineering / <i>Timothy C. Granata and Jay F. Martin</i> ...	2600
Wind Erosion: Climate Change / <i>Alan Busacca and David Chandler</i>	2603
Wind Erosion: Control Measures / <i>Gary L. Tibke</i>	2609
Wind Erosion: Environmental Effects / <i>R. Scott Van Pelt</i>	2614
Wind Erosion: Field Measurement / <i>R. Scott Van Pelt and Ted M. Zobeck</i>	2618
Wind Erosion: Global Hot Spots / <i>Andrew Warren</i>	2625
Wind Erosion: Micrometeorology / <i>Giles F.S. Wiggs</i>	2628
Wind Erosion: Modeling / <i>Lawrence J. Hagen</i>	2632
Wind Erosion: Principles / <i>Larry D. Stetler</i>	2636
Wind Erosion: Soil Quality and Productivity / <i>John Leys</i>	2640
Windblown Dust / <i>Dale Gillette</i>	2644
Wind-Driven Rain: Erosion / <i>Gunay Erpul, L. Darrell Norton, and Donald Gabriels</i>	2647
World Reference Base for Soil Resources / <i>Peter Schad and Stefaan Dondeyne</i>	2650

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

Topical Table of Contents

Agriculture

Agricultural Management: Root Growth / Susanne Schroetter, Jutta Rogasik, and Ewald Schnug	72
Agricultural Soil Carbon: Trading / Bruce A. McCarl, Sung Ju Cho, Jinxiu Ding, Pei Huang, Layla Shiva, and Chin-Hsien Yu	76
Biofuels versus Agricultural Soils / David Pimentel	213
Bunch Planting: Water Conservation / B.A. Stewart	261
Culture: Soil-less / Nazim Gruda, Giorgio Prosdocimi Gianquinto, Yuksel Tuzel, and Dimitrios Savvas	533
Growing Media / Nazim Gruda, Jean Caron, Munoo Prasad, and Michael Maher	1053
No Till / Paul W. Unger	1566
Organic Fertilization: Heavy Metal Uptake / Ewald Schnug, Alexandra Izosimova, and Renata Gaj	1621
Plant Growth: Oxygen Diffusion Rate / Witold Stepniewski	1725
Root Growth: Pressure at the Soil—Root Interface / Rabi K. Misra	1957
Root Monitoring System / Zhikuan Jia, Pute Wu, Qingfang Han, Junfeng Nie, Ruixia Ding, and Yufeng Zou	1960
Sugarcane Fields: Harvest Systems and Residue Management / Newton La Scala, Jr., Ricardo De Oliveira Bordonal, Eduardo Barretto De Figueiredo, Alan Rodrigo Panosso, Mara Regina Moitinho, and Mariana Marotti Corradi	2231
Sustainable Agriculture: Social Aspects / Frederick H. Buttel	2273
Sustainable Agriculture: Soil Quality / John W. Doran and Ed G. Gregorich	2276
Tillage: Gas Exchange / Donald C. Reicosky	2348
Tilth / Jerry L. Hatfield	2351

Biological Effects

Biological Crusts / Jayne Belnap	216
Biotechnology / Manas R. Banerjee and Laila Yesmin	243
Organisms and Soil Food Webs / David C. Coleman	1624
Organo-Mineral Relationships / Claire Chenu, Alain F. Plante, and Pascale Puget	1629
Spectral Mixtures: Soil—Plant / Alfredo R. Huete	2197

Animals

Animals: Ecosystem Functioning / Alan J. Franzhuebbers	138
Animals: Microbial Interactions and Nutrient Cycling / Lisa Cole and Richard D. Bardgett	142
Fauna / Mary C. Savin	871
Fauna and Microflora: Macrofauna / Judy Tisdall	877

Biochar

Biochar and Soil Characteristics / Atanu Mukherjee and Rattan Lal	184
Biochar and Soil Quality / David A. Laird and Jeffrey M. Novak	189
Biochar: Soil Carbon and Fertility / Adam O'Toole and Daniel Rasse	193
Fire and Soils / Partap K. Khanna and John Raison	926

Biological Effects (*cont'd.*)

Fungi

Fungi / <i>Serita Frey</i>	979
Mycorrhiza of Forest Ecosystems / <i>Ian A. Dickie</i>	1502
Mycorrhizae: Soil Quality / <i>Ibrahim Ortaş</i>	1505

Insects

Ants / <i>Walter G. Whitford</i>	150
Collembola / <i>Steve P. Hopkin</i>	448
Insect Survival: Subzero Temperature / <i>Mike M. Ellsbury</i>	1217
Mites / <i>Hans Klompen</i>	1488
Termites / <i>David E. Bignell and John A. Holt</i>	2309

Microbes

Actinobacteria / <i>Marketa Šágová-Marecková and Jan Kopecký</i>	40
Bacteria / <i>Mary Ann Bruns</i>	175
Biota / <i>Lev O. Karpachevsky and Mikhail Karpachevsky</i>	235
Biota and Disease-Suppressive Soils / <i>Nicola Lorenz</i>	239
Microbial Communities / <i>K.R. Islam and S.R. Wright</i>	1433
Protozoa / <i>Bryan S. Griffiths</i>	1828

Plants

Village Bamboos / <i>Arun Jyoti Nath, Ashesh Kumar Das, and Rattan Lal</i>	2459
---	------

Soil Organic Matter

Soil Organic Matter (SOM) / <i>Rattan Lal</i>	2108
Soil Organic Matter (SOM): Accumulation / <i>Sylvie A. Quideau</i>	2112
Soil Organic Matter (SOM): Available Water Capacity / <i>Tom G. Huntington</i>	2117
Soil Organic Matter (SOM): Characterization / <i>Christian Feller</i>	2123
Soil Organic Matter (SOM): Composition and Dynamics / <i>Cornelia Rumpel, M.F. Dignac, and Abad Chabbi</i>	2126
Soil Organic Matter (SOM): Global Carbon Cycle / <i>Keith Paustian</i>	2129
Soil Organic Matter (SOM): Global Distribution / <i>Wilfred M. Post</i>	2133
Soil Organic Matter (SOM): Historical Concepts / <i>Christian Feller</i>	2139
Soil Organic Matter (SOM): Landscape / <i>Henry H. Janzen, B.H. Ellert, and D.W. Anderson</i>	2142
Soil Organic Matter (SOM): Management / <i>R. Cesar Izaurralde and Carlos C. Cerri</i>	2147
Soil Organic Matter (SOM): Mass Spectrometry Data Analysis / <i>Nikola Tolic, Malak M. Tfaily, Yufeng Shen, Rosalie Chu, Thomas Fillmore, Rui Zhao, Kent Bloodsworth, Errol Robinson, Ljiljana Paša-Tolić, and Nancy J. Hess</i>	2154
Soil Organic Matter (SOM): Modeling / <i>Peter Smith</i>	2159
Soil Organic Matter (SOM): Molecular Simulations / <i>Amity Andersen</i>	2166
Soil Organic Matter (SOM): Solvent-Based High Resolution Mass Spectrometry / <i>Malak M. Tfaily, Yufeng Shen, Nikola Tolic, Jennifer Kyle, Rosalie Chu, Thomas Fillmore, Rui Zhao, Kent Bloodsworth, Errol Robinson, Ljiljana Paša-Tolić, and Nancy J. Hess</i>	2176
Soil Organic Matter (SOM): Structure and Characterization / <i>Georg Guggenberger</i>	2180
Soil Organic Matter (SOM): Turnover / <i>Johan Six and Julie D. Jastrow</i>	2186

Worms

Earthworms / <i>Patrick J. Bohlen</i>	701
Enchytraeidae / <i>María Jesús Iglesias Briones</i>	723
Nematodes / <i>Christien H. Ettema</i>	1518
Nematodes and Soil / <i>Wilfrida Decraemer</i>	1523
Structure: Earthworms / <i>Martin Shipitalo and Tayfun Korucu</i>	2212

Carbon

Bioenergy Crops: Carbon Balance Assessment / <i>Rocky Lemus and Rattan Lal</i>	210
Carbon Assessment: Spectroscopic Methods / <i>James B. Reeves III and Gregory W. McCarty</i>	270
Carbon Sink Capacity: Soil Profile Characteristics / <i>Yuri Lopes Zinn</i>	315
Carbon: Inelastic Neutron Scattering / <i>Lucian Wielopolski</i>	319
Carbon: Laser-Induced Breakdown Spectroscopy / <i>Michael H. Ebinger, Ronny D. Harris, and Clifton W. Meyer</i>	323
Carbon: Physical Protection / <i>Jennifer A.J. Dungait and David W. Hopkins</i>	327
Carbonates / <i>Douglas W. Ming</i>	331
Carbonates: Water and / <i>Michael Duniway</i>	339
Cycling: Carbon and Nitrogen (C/N) / <i>Sylvie M. Brouder and Ronald F. Turco</i>	538
Ecology: Cycling of Carbon and Nitrogen / <i>Alan J. Franzluebbers</i>	711
Geologic Carbon Capture and Storage / <i>Sean I. Plasynski, John T. Litynski, Timothy R. Carr, Howard G. McIlvried, and Rameshwar D. Srivastava</i>	992
Low-Carbon Technology: Brazilian Semi-arid Ecosystems / <i>Antonio Pereira Filho, Vanderlise Giongo, Tony Jarbas Ferreira Cunha, Jose Texeira Filho, Tayane de Lima Santos, and Luiz Fernando Carvalho Leite</i>	1377
Mine Soils: Measuring Geogenic Carbon / <i>David A.N. Ussiri and Rattan Lal</i>	1449
Quality: Carbon and Nitrogen Gases / <i>Philippe Rochette, Reynald Lemke, and Sean McGinn</i>	1848
Soil Organic Matter (SOM): Global Carbon Cycle / <i>Keith Paustian</i>	2129

Carbon Sequestration

Carbon Sequestration: Fish Ponds / <i>Subhendu Adhikari and Rattan Lal</i>	274
Carbon Sequestration: Geologic / <i>Eswaran Padmanabhan</i>	279
Carbon Sequestration: Iceland / <i>Anna María Ágústssdóttir</i>	284
Carbon Sequestration: Nutrient Management / <i>M.C. Manna, Muneshwar Singh, R.H. Wanjari, Asit Mandal, and A. K. Patra</i>	288
Carbon Sequestration: Sediments / <i>Eswaran Padmanabhan</i>	294
Carbon Sequestration: Semi-arid Regions of India / <i>Cherukumalli Srinivasa Rao, Sumanta Kundu, and Srinivas K.</i>	299
Carbon Sequestration: Urban Ecosystems / <i>Adam Louis Selhorst</i>	307
Carbonates: Secondary and Pedogenic / <i>Ahmet R. Mermut and A. Landi</i>	335
Climate Change: Soil Carbon Sequestration / <i>Sherwood E. Idso and Keith E. Idso</i>	442
Mine Soils: Reclamation and Soil Carbon Sequestration / <i>Vasant A. Akala and Rattan Lal</i>	1466
Pyrogenic Carbon / <i>Barry G. Rawlins</i>	1834
Soil Carbon Sequestration: Ethiopia / <i>Ambachew Demessie, Bal Ram Singh, and Rattan Lal</i>	2066
Weathering: Carbon Sequestration / <i>William Berry Lyons, Jerry M. Bigham, Anne E. Carey, and Rattan Lal</i>	2563
Wetlands: Carbon Sequestration / <i>Virginie Bouchard and Matthew Cochran</i>	2576

Soil Inorganic Carbon

Inorganic Carbon: Analysis / <i>Richard R. Drees and C. Tom Hallmark</i>	1191
Inorganic Carbon: Climate and Time / <i>Lee C. Nordt</i>	1195
Inorganic Carbon: Composition and Formation / <i>H. Curtis Monger and Larry P. Wilding</i>	1199

Carbon Sequestration (*cont'd.*)

Inorganic Carbon: Global Carbon Cycle / William H. Schlesinger	1203
Inorganic Carbon: Global Stocks / Larry P. Wilding, Lee C. Nordt, and John M. Kimble	1206
Inorganic Carbon: Land Use Impacts / Donald L. Suarez	1210
Inorganic Carbon: Modeling / Leslie D. McFadden and Ronald G. Amundson	1213

Soil Organic Carbon

Organic Carbon: Assessment Methods / K.R. Islam	1604
Organic Carbon: Sequestration Concepts / Kenneth R. Olson	1609
Organic Carbon: Subsoil Pools / Klaus Lorenz and Rattan Lal	1614

Chemical Attributes

Allophanes / Leslie Louise Baker and Jodi Johnson-Maynard	97
Chemical Composition / Goro Uehara	348
Chemisorption / N.J. Barrow	353
Enzymes / Veronica Acosta-Martinez and Susanne Klose	737
Fertilizers: Mineral / L.L. Hammond and Balu L. Bumb	910
Ion Exchange / Bryon W. Bache	1241
Liming and Lime Materials / Mark K. Conyers	1362
Minerals: Amorphous / April L. Ulery	1469
Minerals: Primary / Nikolaos I. Barbayiannis and Vissarion Z. Keramidas	1473
Minerals: Secondary / Deborah A. Soukup	1476
Minerals: Solubility / Wayne P. Robarge	1480
pH / Grant W. Thomas	1695
Pyrite / Michael J. Borda	1831
Redox Phenomena / Bruce R. James	1896
Sesquioxides / Joey N. Shaw and Larry T. West	2003
Soil Enzymes / Cherukumalli Srinivasa Rao, Minakshi Grover, Sumanta Kundu, and Susheelendra Desai	2100
Soluble Salts: Translocation and Accumulation / Jimmie L. Richardson	2192
Solute Transport / Arne E. Olsen and James W. Jawitz	2194
Urea: Subsoiling and Controlled Release / Tangyuan Ning, Rattan Lal, Zengjia Li, and Min Zhang	2411
Variable Charge Soils: Mineralogy and Chemistry / Eric Van Ranst, Nikolla P. Qafoku, Andrew Noble, and Ren-kou Xu	2432

Clays

Clay Minerals / C.D. Barton and Anastasios D. Karathanasis	421
Clay Minerals: Charge Properties / Christopher John Matocha	426
Clay Minerals: Weathering and Alteration of / Anastasios D. Karathanasis	430

Metals

Aluminum / Johannes Bernhard Wehr, Frederick Paxton Cardell Blamey, and Neal William Menzies	105
Boron and Molybdenum / Umesh C. Gupta and J.A. MacLeod	252
Calcification / Janis L. Boettinger	264
Calcium / Zdenko Rengel	267
Cobalt and Iodine / Ronald G. McLaren	445
Heavy Metals / Mike J. McLaughlin	1089
Iron Oxides / Nikolla P. Qafoku and James Amonette	1245
Magnesium / N.S. Bolan, K. Arulmozhiselvan, and P. Paramasivam	1392

Manganese: Brazilian Soils / <i>Diego Antonio França de Freitas, Nilton Curi, and Nestor Kämpf</i>	1396
Metal–Clay Interactions / <i>Dean Hesterberg</i>	1426
Organic Fertilization: Heavy Metal Uptake / <i>Ewald Schnug, Alexandra Izosimova, and Renata Gaj</i>	1621
Selenium / <i>Gunnar Gissel-Nielsen</i>	1995
Strontium / <i>Silvia H. Haneklaus and Ewald Schnug</i>	2203
Trace Metal Contamination / <i>Åsgeir Rossebø Almås and Bal Ram Singh</i>	2364
Urban Wastewater for Irrigation: Heavy Metals / <i>P.S. Minhas and K. Lal</i>	2407

Other Elements

Antimony / <i>Gudny Okkenhaug and Jan Mulder</i>	146
Arsenic: Southeast Asia / <i>Mohammad Mahmudur Rahman and Ravi Naidu</i>	161
Chlorine / <i>Uzi Kafkafi and Guohua Xu</i>	362
Gypsic Soils / <i>Juan Herrero and Jaime Boixadera</i>	1064
Gypsic Soils: Gypsum Formation / <i>Ahmet R. Mermut and Hossein Khademi</i>	1068
Nitrate Leaching Index / <i>Harold M. van Es and Jorge A. Delgado</i>	1535
Nitrate Leaching Management / <i>John J. Meisinger, Jorge A. Delgado, and Ashok Alva</i>	1538
Rare Earth Elements / <i>Zhengyi Hu, Gerd Sparovek, Silvia H. Haneklaus, and Ewald Schnug</i>	1891

Sodic Soils

Salt-Affected Soils / <i>Anna Eynard, Rattan Lal, and Keith D. Wiebe</i>	1965
Sodic Soils / <i>Pichu Rengasamy</i>	2029
Sodic Soils: Formation and Global Distribution / <i>Brian Murphy</i>	2032
Sodic Soils: Humid Regions / <i>Samuel J. Indorante</i>	2037
Sodic Soils: Physical Properties and Behavior / <i>Hwat Bing So</i>	2044
Sodic Soils: Processes, Characteristics, and Classification / <i>Pichu Rengasamy</i>	2048
Sodic Soils: Reclamation / <i>Jock Churchman</i>	2051
Sodicity: Subsoil / <i>Kwong Yin Chan</i>	2056

Sulfur and Sulfates

Sulfate and Sulfide Minerals / <i>Delvin S. Fanning and Steven N. Burch</i>	2238
Sulfur / <i>Ewald Schnug, Silvia H. Haneklaus, and Elke Bloem</i>	2241
Sulfur: Chemical Behavior in the Rhizosphere / <i>Zhengyi Hu, Silvia H. Haneklaus, and Ewald Schnug</i>	2247
Sulfur: Nutrition / <i>Silvia H. Haneklaus, Elke Bloem, and Ewald Schnug</i>	2251

Classifications

Taxonomies: U.S. Soil Taxonomy and Indian Scenario / <i>Tapas Bhattacharyya and Dilip Kumar Pal</i>	2291
Taxonomy / <i>Mark H. Stolt</i>	2295

Classification Systems

Classification Systems / <i>Stephen Nortcliff</i>	367
Classification Systems: Arab Traditional, Moroccan Case / <i>Mohamed Sabir and Hassan Ben Jelloun</i>	370
Classification Systems: Australian and New Zealand / <i>Terry A. Isbell and A.E. Hewitt</i>	375
Classification Systems: Brazilian / <i>A.C.S. da Costa and M.R. Nanni</i>	379
Classification Systems: Canadian / <i>Charles Tarnocai</i>	383
Classification Systems: Chinese / <i>Zi-Tong Gong</i>	389
Classification Systems: French / <i>Jean-Paul Legros</i>	391
Classification Systems: Historical Developments / <i>Dan H. Yaalon</i>	395

Classifications (*cont'd.*)

Classification Systems: Indian / Mariappan Velayutham, Tapas Bhattacharyya, and Dilip Kumar Pal	398
Classification Systems: Indigenous / Erhan Akça and Selim Kapur	402
Classification Systems: Major / Lars Krogh	406
Classification Systems: Netherlands / Alfred E. Hartemink and Henk de Bakker	412
Classification Systems: Russian / Maria Gerasimova	415
Classification Systems: South African / Jeffrey C. Hughes	418

Types of Soils

Alfisols / Rienk Miedema	92
Andisols / Jon Chorover	130
Andisols: Iceland / Olafur Arnalds	134
Arid Soils / H. Curtis Monger	157
Chernozems / Boris Boincean and Rattan Lal	356
Entisols / Larry T. West	728
Gelisols / James G. Bockheim	989
Grasslands Soils / Douglas D. Malo	1029
Hard-Setting Soils / Richard S.B. Greene	1072
Histosols / David L. Lindbo and Deborah A. Kozlowski	1107
Inceptisols / John M. Galbraith, Kenneth Scheffe, and Shawn McVey	1151
Loess / Fred E. Rhoton and Helaine W. Markewich	1365
Loess Plateau / Fenli Zheng, Ximeng Xu, and Xiubin He	1370
Oxisols / Stanley W. Buol	1635
Peatlands / Dale H. Vitt and Paul Short	1668
Permafrost: Soil Temperature and Special Problems / Douglas Kane and Julia Boike	1687
Petrocalcic Horizons / Alain Ruellan	1691
Plinthite and Petroplinthite / Eswaran Padmanabhan and Hari Eswaran	1743
Podzols / Peter Buurman	1747
Rendzina / Thomas E. Fenton	1907
Serpentinitic Soils / Rebecca Burt and Michael A. Wilson	1999
Spodosols / Delbert Mokma	2200
Terra Preta (Black Earths) / Kurt Spokas, Jose Marques Jr., Newton La Scala Jr., Ed Nater, and Diego S. Siqueira	2312
Terra Preta de Indio / Johannes Lehmann	2316
Ultisols / Joey N. Shaw	2380
Vertisols / Wouter A. Blokhuis	2440
Vertisols: Surface Crack Management / J. Somasundaram, Nishant K. Sinha, Ashok K. Patra, and Rattan Lal	2450

Desertification

Desertification: Biological Productivity Decline / Uriel N. Safriel	608
Desertification: Extent / Victor R. Squires	616
Desertification: Greenhouse Effect / Craig Idso and Sherwood E. Idso	620
Desertification: Humid Environment in Iceland / Andres Arnalds	623
Desertification: Impact / David A. Mouat and Judith Lancaster	628
Desertification: Mapping Constraints and Challenges / Pandi Zdruli, Michael Cherlet, and Claudio Zucca	633
Desertification: Prevention and Restoration / Claudio Zucca, Susana Bautista, and Franco Previtali	642
Desertification: Productivity / Kris M. Havstad	645

Desertification: Restoration / <i>Alon Tal</i>	648
Desertification: Reversal / <i>David Tongway and John Ludwig</i>	654
Drought: Drought Resistance / <i>Graeme C. Wright and Nageswararao C. Rachaputi</i>	693
Drought: Precipitation, Evapotranspiration, and Soil Moisture / <i>Joshua B. Fisher and Konstantinos M. Andreadis</i>	698

Ecological Concerns

Amendments and Ameliorants / <i>David C. McKenzie</i>	114
Biodiversity and Sustainability / <i>Odo Primavesi</i>	205
Climate / <i>Alexander N. Gennadiyev and Serge S. Chernyanskii</i>	435
Ecology: Cycling of Carbon and Nitrogen / <i>Alan J. Franzluebbers</i>	711
Ecosystems: Life Attributes and Environment / <i>Dennis R. Linden</i>	719
Environmentally Friendly Indigenous Technologies / <i>Selim Kapur and Erhan Akça</i>	732
Fire and Soils / <i>Partap K. Khanna and John Raison</i>	926
Landslide and Landcreep / <i>Jau-Yau Lu and Hao-Jung Shieh</i>	1348
Leaching and Illuviation / <i>Lynn E. Moody</i>	1358
Resilience / <i>Moses M. Tenywa, J.G.M. Majaliwa, and A. Lufafa</i>	1909
Resilience: Quality and / <i>Rattan Lal</i>	1918
Resilience: Restoration / <i>F.W.T. Penning de Vries and Eric T. Craswell</i>	1924
Sustainable Development and Sustainability / <i>Alan D. Hecht and Joseph Fiksel</i>	2280

Climate Change

Climate Change: Gas Fluxes / <i>Pascal Boeckx and Oswald Van Cleemput</i>	438
Climate Change: Soil Carbon Sequestration / <i>Sherwood E. Idso and Keith E. Idso</i>	442
Erosion: Global Change / <i>Xingxiang Wang, Taolin Zhang, Longxi Cao, and Yin Liang</i>	804
Greenhouse Effect / <i>Rattan Lal</i>	1048

Conservation

Conservation Tillage / <i>Jack Cline and Robert Hendershot</i>	462
Conserved Lands: Stewardship / <i>Peter August, Janet Coit, and David Gregg</i>	466
Protection: Policy of the European Union / <i>Irene L. Heuser and Luca Montanarella</i>	1823
Soil Conservation: Incentives / <i>David Sanders</i>	2081
Soil Conservation: Strategies / <i>Winfried E.H. Blum</i>	2084
Soil Conservation: U.S. Historical Perspective / <i>Dana D. York</i>	2086

Greenhouse Gases

Ammonia: Volatilization from Agricultural Soils / <i>Paul G. Saffigna and John R. Freney</i>	117
Erosion: Carbon Dioxide / <i>Pierre A. Jacinthe and Rattan Lal</i>	777
Nitrous Oxide Emissions: Agricultural Soils / <i>John R. Freney</i>	1555
Nitrous Oxide Emissions: Paddy Soils / <i>Jianfu Xue, Xin Zhao, and Hailin Zhang</i>	1559
Nitrous Oxide Emissions: Sources, Sinks, and Strategies / <i>Katsu Minami</i>	1562
Power Plants: Carbon Dioxide Capture / <i>Sean I. Plasynski, Thomas J. Feeley, Timothy Fout, Howard G. McIlvried, and Rameshwar D. Srivastava</i>	1798
Rice Paddies: Methane Emissions / <i>Ronald L. Sass</i>	1940
Rice Paddies: Methane Emissions, Mitigating / <i>Kazuyuki Yagi</i>	1943
Salt-Affected Soils: Nitrous Oxide Emissions / <i>G.S. Dheri, B.S. Brar, and Debankur Sanyal</i>	1969
Wetlands: Methane Emission / <i>Anna Ekberg and Torben Røjle Christensen</i>	2596

Ecological Concerns (*cont'd.*)

Pollution

Pollution / <i>Zulkuf Kaya</i>	1758
Pollution: Industrial Waste / <i>Winfried E.H. Blum, Walter W. Wenzel, Wolfgang Friesl-Hanl, and Martin H. Gerzabek</i>	1762
Pollution: Non-Point Source / <i>Ravendra Naidu, Mallavarapu Megharaj, Peter Dillon, Rai Kookana, Ray Correll, and Walter W. Wenzel</i>	1765
Pollution: Organic and Inorganic / <i>A. Paul Schwab</i>	1768
Pollution: Persistent Organic / <i>Mark Radosevich and E. Danielle Rhine</i>	1771
Pollution: Point Source / <i>Ravendra Naidu, Mallavarapu Megharaj, Peter Dillon, Rai Kookana, Ray Correll, and Walter W. Wenzel</i>	1776
Radionuclides / <i>Philip M. Jardine</i>	1876
Surface Water: Pollution by Nitrogen Fertilizers / <i>Gregory McIsaac</i>	2268
Uranium Contamination / <i>Ewald Schnug, Roberta Bottino Montolar Sparovek, Maria del Carmen Lamas, Sylvia L. Kratz, Jurgen Fleckenstein, and Susanne Schroetter</i>	2385
Windblown Dust / <i>Dale Gillette</i>	2644

Restoration and Rehabilitation

Biodegradation and Bioremediation / <i>Owen P. Ward and Ajay Singh</i>	198
Land Restoration / <i>Richard W. Bell</i>	1304
Landfill Sites: Revegetation / <i>Gilbert Yuk-sing Chan and Ming H. Wong</i>	1322
Phytoremediation / <i>Khan Towhid Osman and Md. Abul Kashem</i>	1717
Rehabilitation: Indicators and Monitoring / <i>David Jasper</i>	1899
Restoration Ecology / <i>Richard Hobbs</i>	1932
Restoration: Success and Completion Criteria / <i>Sam C. Ward</i>	1935
Tailings: Minerals Processing Residue Rehabilitation / <i>Lloyd R. Hossner and Hamid Shahandeh</i>	2286
Waste Rock and Overburden Dumps: Rehabilitation / <i>Martin V. Fey, R.D. O'Brien, and A.J. Mills</i>	2464

Erosion

Erosion / <i>Dennis C. Flanagan</i>	742
Erosion Management: Hill Soils / <i>Narendra Kumar Lenka and B. Krishna Rao</i>	746
Erosion Tolerance / <i>David L. Schertz and Mark A. Nearing</i>	753
Erosion: Aggregate Breakdown Mechanisms / <i>Yves Le Bissonnais</i>	757
Erosion: Agronomic Practices / <i>Glenn A. Weesies, David L. Schertz, and William F. Kuenstler</i> ...	762
Erosion: Assessment / <i>John Boardman</i>	767
Erosion: Carbon Dioxide / <i>Pierre A. Jacinthe and Rattan Lal</i>	777
Erosion: Crop Yield / <i>Michael Stocking</i>	786
Erosion: Disturbed Lands / <i>William J. Elliot</i>	790
Erosion: Effects on Human Life / <i>Neroli Pedro Cogo and Renato Levien</i>	794
Erosion: Global Change / <i>Xingxiang Wang, Taolin Zhang, Longxi Cao, and Yin Liang</i>	804
Erosion: On-Site and Off-Site Impacts / <i>Jerry L. Hatfield</i>	811
Erosion: Overland Research and Measurement Techniques / <i>Chia Chun Joseph Wu</i>	814
Erosion: Perennial Crop Plantations / <i>Alfred E. Hartemink</i>	819
Erosion: Soil Conservation / <i>Eric T. Craswell</i>	834
Erosion: Water Quality / <i>Andreas Klik</i>	838
Erosivity and Erodibility / <i>Peter I.A. Kinnell</i>	845
Gully Erosion / <i>Fenli Zheng, Chihua Huang, and Ximeng Xu</i>	1059
Landscape: Development and Erosion / <i>Jon Harbor</i>	1336
Quality: Erosion / <i>Craig Ditzler</i>	1856

Sedimentation

Erosion: Sedimentation Control Amendment Techniques / <i>X.-C. (John) Zhang</i>	823
Erosion: Sedimentation Control Vegetative Techniques / <i>Samson D. Angima</i>	827
Sedimentation Control and Erosion: Engineering Techniques / <i>Jose Miguel Reichert and Elemar Antonino Cassol</i>	1986

Tillage

Tillage Erosion: Description and Process / <i>Michael J. Lindstrom</i>	2330
Tillage Erosion: Measurement Techniques / <i>David A. Lobb</i>	2333
Tillage Erosion: Properties and Productivity Effects / <i>Tom E. Schumacher</i>	2336
Tillage Erosion: Relationship to Water Erosion / <i>Gerard Govers</i>	2339
Tillage Erosion: Terrace Formation / <i>Seth M. Dabney and Dalmo A.N. Vieira</i>	2342

Water

Erosion: Controlling Irrigation-Induced / <i>Robert E. Sojka and David L. Bjorneberg</i>	782
Erosion: Snowmelt / <i>Donald K. McCool</i>	831
Raindrop Impact and Splash Erosion / <i>Hossein Ghadiri</i>	1881
Torrential Erosion: Himalayas / <i>Ram Prashad Yadav</i>	2358
Water Erosion / <i>David Favis-Mortlock</i>	2485
Water Erosion: Empirical Models / <i>John M. Laflen</i>	2489
Water Erosion: Hybrid Models / <i>Jeffrey G. Arnold, Kevin W. King, and Jimmy R. Williams</i>	2494
Water Erosion: Modeling / <i>Calvin W. Rose</i>	2499
Water Erosion: Process-Based Modeling / <i>Mark A. Nearing</i>	2504

Wind

Erosion: Fly-Ash Spheres as Time Marker / <i>Kenneth R. Olson and Alexander N. Gennadiyev</i>	798
Wind Erosion: Climate Change / <i>Alan Busacca and David Chandler</i>	2603
Wind Erosion: Control Measures / <i>Gary L. Tibke</i>	2609
Wind Erosion: Environmental Effects / <i>R. Scott Van Pelt</i>	2614
Wind Erosion: Field Measurement / <i>R. Scott Van Pelt and Ted M. Zobeck</i>	2618
Wind Erosion: Global Hot Spots / <i>Andrew Warren</i>	2625
Wind Erosion: Micrometeorology / <i>Giles F.S. Wiggs</i>	2628
Wind Erosion: Modeling / <i>Lawrence J. Hagen</i>	2632
Wind Erosion: Principles / <i>Larry D. Stetler</i>	2636
Wind Erosion: Soil Quality and Productivity / <i>John Leys</i>	2640
Wind-Driven Rain: Erosion / <i>Gunay Erpul, L. Darrell Norton, and Donald Gabriels</i>	2647

Fertility

Biochar: Soil Carbon and Fertility / <i>Adam O'Toole and Daniel Rasse</i>	193
Crop Plants: Phosphorus Availability / <i>Bettina Eichler-Löbermann and Ewald Schnug</i>	494
Cycling: Carbon and Nitrogen (C/N) / <i>Sylvie M. Brouder and Ronald F. Turco</i>	538
Fertility Decline: Definitions and Assessment / <i>Alfred E. Hartemink</i>	880
Fertility: Environmentally Compatible Management / <i>Bal Ram Singh</i>	884
Fertility: Evaluation Systems / <i>Ram C. Dalal and A. Subba Rao</i>	890
Fertility: Low Input and Traditional Maintenance Methods / <i>Miguel Altieri</i>	894
Fertility: North China Plains / <i>Xiangbin Kong and Rattan Lal</i>	899
Nutrient Management: Fertility and / <i>John L. Havlin</i>	1576
Phosphorus / <i>John Ryan and Abdul Rashid</i>	1700
Phosphorus: Manure and Diet Modification / <i>Rory O. Maguire, John T. Brake, and Peter W. Plumstead</i>	1705

Fertility (*cont'd.*)

Phosphorus: Manure and Diet Modification / Rory O. Maguire, John T. Brake, and Peter W. Plumstead	1705
Phosphorus: Plant Nutrition and Microorganism Contribution / Bettina Eichler-Löbermann, Christel Baum, Silke Ruppel, and Ewald Schnug	1708
Phosphorus: Spatial Speciation in Agricultural Soils / Anja Gassner and Ewald Schnug	1712
Potassium / Philippe Hinsinger	1786
Potassium: Dynamics and Mineralogy / A.V. Shanwal and S.S. Dahiya	1791
Potassium: Nutrition in Semi-Arid Tropics / D.L. Oswalt	1796

Biological Nitrogen Fixation

Biological Nitrogen Fixation / Robert H. Burris	220
Biological Nitrogen Fixation: Contributions to Agriculture / Mark B. Peoples	223
Biological Nitrogen Fixation: Enhancement Techniques / David Francis Herridge	227
Biological Nitrogen Fixation: Forms and Regulating Factors / Ken E. Giller and Paul Mapfumo	232
Nitrogen and its Transformations / Oswald Van Cleemput and Pascal Boeckx	1541
Nitrogen Index / Jorge A. Delgado	1545
Nitrogen-15: Utilization / Jorge Benitez-Vega, Luis López-Bellido, Ramón Redondo, and Rafael J. López-Bellido	1551

Fertilizers

Fertilizers: Application Methods / John Ryan	903
Fertilizers: Leaching Losses / Paul G. Saffigna and Ian R. Phillips	907
Fertilizers: Organic / Gary J. Gascho	916
Fertilizers: Types and Formulations / Douglas Robert McGuffog	919
Fertilizers: Urban Waste and Sludges / Rory O. Maguire and James Thomas Sims	923
Liming and Lime Materials / Mark K. Conyers	1362
Manure Management: Gaseous Emissions / Veerasamy Sejian, Lipismita Samal, M. Bagath, R.U. Suganthi, Raghavendra Bhatta, and Rattan Lal	1400
Manure: Compost and Biosolids / Bahman Eghball and Kenneth A. Barbarick	1406
Nanofertilizers / Ruiqiang Liu and Rattan Lal	1511

Micronutrients

Animals: Microbial Interactions and Nutrient Cycling / Lisa Cole and Richard D. Bardgett	142
Carbon Sequestration: Nutrient Management / M.C. Manna, Muneshwar Singh, R.H. Wanjari, Asit Mandal, and A.K. Patra	288
Integrated Nutrient Management / Bal Ram Singh and Ram C. Dalal	1221
Integrated Nutrient Management: Sustainability / G.S. Saroa and Rattan Lal	1227
Micronutrients and Human Health / Ram Phal Narwal, R.S. Malik, S.K. Malhotra, and Bal Ram Singh	1443
Nutrient Management / Jorge A. Delgado	1570
Nutrient Management: Fertility and / John L. Havlin	1576
Nutrients: Deficiency and Toxicity Symptoms / Noel J. Grundon	1585
Nutrients: Diffusion, Bioavailability, and Plant Uptake / Niels Erik Nielsen	1588
Nutrients: Interactions in Soil—Plant System / Fusuo S. Zhang, J. Shen, and Y.-G. Zhu	1594
Nutrients: Water Interactions / Ardell D. Halvorson	1597
Plant Nutrients / Volker Roemheld	1728
Plant Nutrients: Intensity, Quantity, and Buffer Power / Ram C. Dalal	1731
Plant Nutrients: Sufficiency and Requirements / Kanwar L. Sahrawat	1735
Precision Agriculture: Nutrient Cycling / Robert J. Lascano	1811

Soil Organic Matter (SOM): Nutrient Dynamics / Charles W. Rice	2172
Variable Charge Soils: Mineralogy and Chemistry / Eric Van Ranst, Nikolla P. Qafoku, Andrew Noble, and Ren-kou Xu	2432

Minerals

Boron and Molybdenum / Umesh C. Gupta and J.A. MacLeod	252
Copper / Judith F. Pedler and David R. Parker	481
Food Crops: Zinc and Iron Biofortification / Yashbir Singh Shivay and Rajendra Prasad	933
Iron Oxides / Nikolla P. Qafoku and James Amonette	1245
Selenium / Gunnar Gissel-Nielsen	1995
Silica: Pedogenic Accumulation / Katherine J. Kendrick	2012
Silicon and Sodium / Jian Feng Ma	2015

General Topics

Accounting: Emergy Analysis / J.F. Martin and D.R. Tilley	1
Care of Soil / Delia C. Catacutan	342
Economics of Soil Management: U.S. / Jeffrey W. Hopkins	716
Ethics / John Ronald Engel	848
Geology and Soil / Kenneth R. Olson	997
Land Forms / Carolyn G. Olson	1294
Landscape / George Hall	1327
Landscape: Classification / Philip Schoeneberger	1331
Landscape: Elements / Douglas Wysocki and C. William Zanner	1339
Landscape: Relationships / Timothy A. Quine	1344
Materials and Soils / Selim Kapur, Erhan Akça, and Takanori Nagano	1416
Rocks / Vsevolod V. Dobrovolsky	1953
Time and Space: Soils in / Neil E. Smeck and C. Lee Burras	2353

History

Future of Soil Science / Eric C. Brevik, Samuel J. Indorante, Dylan E. Beaudette, and Richard W. Arnold	982
History of Soil Science / Eric C. Brevik and Artemi Cerdà	1093
History of Soil Science: 1927–2000 / Fred P. Miller	1098
History of Soil Science: Early to Mid–20th Century / John P. Tandarich	1103
Land Use: Historic / J. Douglas Helms, Hari Eswaran, and Paul Reich	1308

Human Relationship to Soil

Archaeology / John E. Foss	154
Art and Soil / Christian Feller	168
Degradation: Food Security and Poverty / Pierre Crosson	574
Erosion: Effects on Human Life / Neroli Pedro Cogo and Renato Levien	794
Food Security and Soil Water Management / Mark W. Rosegrant, Ephraim Nkonya, and Rowena A. Valmonte-Santos	939
Health / Robin F. Harris and D.E. Romig	1076
Human Culture and Soils / Daniel Hillel	1112
Human Dimensions: Soil Sustainability / Mary Seely, Patrik Klintonberg, and Claus Hager	1115
Human Health and Soil / Charles F. Sing and David B. Sing	1118
Human Society and Soil / Rattan Lal	1123
Human Society and the Planet: Soil as a Heritage / Fred P. Miller	1127
Law and Legal Issues / Ian Hannam and Ben Boer	1352
Law and Legal Issues: Land as Property / Paul Martin and John Page	1355

General Topics (*cont'd.*)

Micronutrients and Human Health / <i>Ram Phal Narwal, R.S. Malik, S.K. Malhotra, and Bal Ram Singh</i>	1443
Modern Civilization and Soils / <i>Kenneth R. Olson</i>	1491
Religious Aspects of Soil—Human Relationships / <i>Verena Winiwarter and Winfried E.H. Blum</i>	1903
Social and Behavioral Sciences' Contribution to Soil Science / <i>Sven B. Lundstedt</i>	2026
Value of Soil to Humans / <i>Rattan Lal</i>	2416

Resources

Evolution: Soil Seed Bank / <i>Paul B. Cavers and David Susko</i>	868
Global Resources / <i>Paul Reich and Hari Eswaran</i>	1020
International Soil Reference and Information Centre (ISRIC) / <i>David Dent</i>	1232
International Union of Soil Sciences / <i>Stephen Nortcliff</i>	1237
Natural Resources: Interaction with Soil / <i>Dennis J. Greenland</i>	1516
Nexus Approach: Resource Management for Soil Productivity / <i>Kai Schwärzel, Reza Ardakanian, Tamara Avellán, and Lulu Zhang</i>	1530
World Reference Base for Soil Resources / <i>Peter Schad and Stefaan Dondeyne</i>	2650

Land Use

Land Use: Land Cover / <i>Andrew K. Skidmore</i>	1313
Land Use: Planning and Geographic Information System (GIS) / <i>Egide Nizeyimana and Jacob Opadeyi</i>	1318
Resilience: Land Use and Soil Management / <i>Soojin J. Park</i>	1913

Croplands and Grazing

Bioenergy Crops: Carbon Balance Assessment / <i>Rocky Lemus and Rattan Lal</i>	210
Cover Crops / <i>Jorge A. Delgado, D. Wayne Reeves, and Ronald F. Follett</i>	484
Crop Evapotranspiration: Measurement System / <i>Huanjie Cai, Pute Wu, Zhijun Li, Xiaotao Hu, and Yufeng Zou</i>	488
Crop Management: Seasonally Frozen Soil / <i>Brenton S. Sharratt</i>	492
Crop Plants: Phosphorus Availability / <i>Bettina Eichler-Löbermann and Ewald Schnug</i>	494
Crop Residue Management / <i>David L. Schertz and Dan Towery</i>	497
Crop Root Response to Temperature: Temperate Zone / <i>Thomas C. Kaspar</i>	501
Crop Rotation and Farming Systems: Temperate Zone / <i>Martin R. Carter</i>	504
Crop Rotation and Farming Systems: Tropical Smallholder Farm Systems / <i>Stefan Hauser, Lindsey Norgrove, and Tarcisius Nyobe</i>	507
Crop Rotation and Farming Systems: Tropics and Subtropics and Swelling Soils / <i>D.M. Freebairn, G.D. Smith, Robin D. Connolly, and Jeff N. Tullberg</i>	512
Croplands / <i>B.A. Stewart</i>	522
Crops: Flooding Tolerance / <i>Tara T. VanToai, Getachew Boru, and Jianhuan Zhang</i>	526
Cultivation: Raised-Bed / <i>Kenneth D. Sayre</i>	529
Eco-Agriculture / <i>Norman Uphoff and Janice E. Thies</i>	706
Grazing Lands: Gaseous Emissions / <i>Lipismita Samal, Veerasamy Sejian, M. Bagath, R.U. Suganthi, Raghavendra Bhatta, and Rattan Lal</i>	1034
Land Husbandry / <i>Francis Shaxson and Malcolm Douglas</i>	1297
Mulch Farming / <i>Rattan Lal</i>	1495
Nanofertilizers / <i>Ruiqiang Liu and Rattan Lal</i>	1511
Organic Agriculture / <i>Kathleen Delate</i>	1600

Food Crops

Food Crops: Zinc and Iron Biofortification / <i>Yashbir Singh Shivay and Rajendra Prasad</i>	933
Food Security: Agricultural Productivity and Resources / <i>Keith D. Wiebe</i>	942
Rice Paddies: Methane Emissions / <i>Ronald L. Sass</i>	1940
Rice Paddies: Methane Emissions, Mitigating / <i>Kazuyuki Yagi</i>	1943
Rice Paddies: Methanogenesis / <i>Ronald L. Sass</i>	1947
Rice Paddies: Soil Management / <i>Xin Zhao, Jianfu Xue, and Hailin Zhang</i>	1950

Precision Agriculture

Precision Agriculture: Engineering Aspects / <i>Joel T. Walker, Reza Ehsani, and Matthew O. Sullivan</i>	1804
Precision Agriculture: Fertilization / <i>Silvia H. Haneklaus and Ewald Schnug</i>	1808
Precision Agriculture: Nutrient Cycling / <i>Robert J. Lascano</i>	1811
Precision Agriculture: Remote Sensing / <i>Kerstin Panten, Holger Lilienthal, Erik Zillmann, Silvia H. Haneklaus, and Ewald Schnug</i>	1815

Forest Land

Boreal Forest / <i>Galina Mazhitova</i>	247
Forest Soils / <i>Nicholas Comerford and Thomas Fox</i>	955
Forest Soils: Calcium Depletion / <i>Tom G. Huntington</i>	959
Forest Soils: Major / <i>Ken Van Rees</i>	963
Forest Soils: Nutrient Cycling / <i>Neil W. Foster and Jagtar S. Bhatti</i>	966
Forest Soils: Properties and Site Productivity / <i>Paul A. Arp and Helmut H. Krause</i>	969
Mycorrhiza of Forest Ecosystems / <i>Ian A. Dickie</i>	1502

Mine Land

Acid Mine Drainage / <i>Jerry M. Bigham and Charles A. Cravotta III</i>	6
Mine Soils: Miscanthus Plantations / <i>Jose G. Guzman and Rattan Lal</i>	1458
Mine Soils: Open Cut Mine Rehabilitation / <i>Douglas J. Dollhopf</i>	1462
Mine Soils: Measuring Geogenic Carbon / <i>David A.N. Ussiri and Rattan Lal</i>	1449
Mine Soils: Reclamation and Soil Carbon Sequestration / <i>Vasant A. Akala and Rattan Lal</i>	1466

Urban Land

Carbon Sequestration: Urban Ecosystems / <i>Adam Louis Selhorst</i>	307
Fertilizers: Urban Waste and Sludges / <i>Rory O. Maguire and James Thomas Sims</i>	923
Industrial Waste / <i>Warren Dick</i>	1178
Urban Lands: Abandoned / <i>Joshua W. Beniston and William D. Shuster</i>	2388
Urban Lands: and Construction Sites / <i>Wolfgang Burghardt</i>	2395
Urban Lands: Management / <i>Klaus Lorenz</i>	2400
Urban Wastewater for Irrigation: Heavy Metals / <i>P.S. Minhas and K. Lal</i>	2407

Wetlands

Wetlands / <i>Ralph W. Tiner</i>	2567
Wetlands: Biodiversity / <i>Jean-Claude Lefevre and Virginie Bouchard</i>	2572
Wetlands: Conservation Policy / <i>Clayton Rubec</i>	2580
Wetlands: Economic Value / <i>Gayatri Acharya</i>	2584
Wetlands: Gaseous Emissions / <i>S.K. Nag</i>	2589
Wetlands: Sedimentation and Ecological Engineering / <i>Timothy C. Granata and Jay F. Martin</i> . . .	2600
Wetlands: Methane Emission / <i>Anna Ekberg and Torben Røjle Christensen</i>	2596
Wetlands: Carbon Sequestration / <i>Virginie Bouchard and Matthew Cochran</i>	2576

Managing Constraints

Acidity

Acid Mine Drainage / Jerry M. Bigham and Charles A. Cravotta III	6
Acid Rain: Nitrogen Deposition / George F. Vance	11
Acid Sulfate Soils / Delvin S. Fanning	17
Acid Sulfate Soils: Distribution and Extent / Wim Andriesse and M.E.F. van Mensvoort	20
Acid Sulfate Soils: Formation / Martin C. Rabenhorst, Delvin S. Fanning, and Steven N. Burch	26
Acid Sulfate Soils: Management / Michael D. Melville, Ian White, and Robert Quirk	31
Acid Sulfate Soils: Problems / Martin C. Rabenhorst and Delvin S. Fanning	36

Air

Aeration: Measurement / Robert E. Sojka and H.D. Scott	44
Aeration: Tillage Effects / Dave J. Horne and Robert E. Sojka	47
Air Permeability / Manoj K. Shukla and Rattan Lal	85
Anaerobic Processes / Paul A. McDaniel and Daniel G. Strawn	126
Respiration / Pierre A. Jacinthe and Rattan Lal	1928

Carbon

Agricultural Soil Carbon: Trading / Bruce A. McCarl, Sung Ju Cho, Jinxiu Ding, Pei Huang, Layla Shiva, and Chin-Hsien Yu	76
Biochar: Soil Carbon and Fertility / Adam O'Toole and Daniel Rasse	193
Mapping Soil Carbon / Budiman Minasny, Brendan Malone, and Alex B. McBratney	1409
Mapping Soil Carbon: Stocks in Turkey / Gönül Aydın, Mehmet Ali Çullu, Sabit Erşahin, Erhan Akça, Emrah Erdoğan, Levent Atatanır, Alper Yorulmaz, Ahmet Çilek, Merve Ersoy, Somayyeh Rezzaghi Miavaghi, Selim Kapur, and Rattan Lal	1412
Soil Carbon Map: Africa / Arwyn Jones, Roland Hiederer, and Luca Montanarella	2059
Soil Carbon Sequestration: Ethiopia / Ambachew Demessie, Bal Ram Singh, and Rattan Lal	2066
Soil Carbon: Compositional and Isotopic Analysis / James Moran, M. Lizabeth Alexander, and Alexander Laskin	2073
Soil Carbon: Farming and Economic Aspects / Bruce A. McCarl	2078

Compaction

Compaction / William E. Wolfe	456
Crop Yield: Compaction / Muhammad Ishaq and Rattan Lal	516

Drainage

Acid Mine Drainage / Jerry M. Bigham and Charles A. Cravotta III	6
Drainage: Aeration and Trafficability / Norman R. Fausey	680
Drainage: Anaerobiosis / Robert O. Evans	683
Drainage: Water Quality / James L. Baker	689

Water

Turfgrass: Protection of Soil and Water / James A. Murphy and Stephanie L. Murphy	2377
Water Conservation / Paul W. Unger	2472
Water Content / Tom J. Jackson	2475
Debris Flow / Jau-Yau Lu	544
Water Content: Passive and Active Microwave Remote Sensing / Eric D. Warner and Gary W. Petersen	2480
Water Infiltration / Manoj K. Shukla and Rattan Lal	2507

Water Management: Computer Modeling / Laj R. Ahuja and Liwang Ma	2510
Water Management: Use Efficiency / David C. Nielsen	2518
Water Measurement: Methods / Des McGarry	2522
Water Range: Least-Limiting / Alvaro Pires da Silva, Beverly D. Kay, Cássio A. Tormena, Silvia Imhoff, Douglas L. Karlen, and Joseph G. Benjamin	2530
Water Retention / Satish C. Gupta and Dong Wang	2535
Water: Plant-Available / Argyrios Gerakis and Joe T. Ritchie	2541
Water-Repellent Soils / Anna Eynard, Rattan Lal, and Keith D. Wiebe	2546
Watershed Approach / Timothy R. Green and Jan van Schilfgaarde	2550
Watershed Management: Remote Sensing and GIS Applications / A.V. Shanwal and S.P. Singh	2555

Measurements, Testing, and Modeling

Color / Robin N. Thwaites	452
Conditioning Index / Ted M. Zobeck, M. Lee Norfleet, and Douglas L. Karlen	459
Consistence / Ray McBride	471
Diagnostic Horizons / E.M. Bridges	668
Geomorphology / Robin N. Thwaites	1000
Geophysical Methods / Barry J. Allred, Viacheslav I. Adamchuk, Raphael A. Viscarra Rossel, Jim Doolittle, Robert S. Freeland, Katherine R. Grote, and Dennis L. Corwin	1004
Geostatistics / Anja Gassner and Ewald Schnug	1012
Hydraulic Conductivity / Jacob H. Dane, Marc Jalbert, and Jan W. Hopmans	1133
Land Capability Analysis / Michael J. Singer	1285
Land Capability Classification / Thomas E. Fenton	1288
Land Evaluation / J. Herbert Huddleston	1291
Pedotransfer Functions / J.H.M. Wösten	1682
Plastic Properties / Gunnar Kirchhof	1740
Radiometric Survey / Barry G. Rawlins and Raphael A. Viscarra Rossel	1872
Rapid Soil Analysis: Diffuse Reflectance Spectroscopy / Keith D. Shepherd and Markus G. Walsh	1886
Soil Organic Matter (SOM): Mass Spectrometry Data Analysis / Nikola Tolic, Malak M. Tfaily, Yufeng Shen, Rosalie Chu, Thomas Fillmore, Rui Zhao, Kent Bloodsworth, Errol Robinson, Ljiljana Paša-Tolić, and Nancy J. Hess	2154
Testing / Yash P. Kalra and Jagtar S. Bhatti	2320
Texture / Harold R. Geering and Hwat Bing So	2323
Variability / Josef H. Görres	2419
Variability: Spatial / Brian Slater	2428

Mapping

Digital Soil Mapping / Budiman Minasny, Alex B. McBratney, and Florence Carré	675
GIS Integration: Remote Sensing / Egide Nizeyimana	1017
Satellite Mapping / Bruce E. Frazier	1972

Measurements

Amoozemeter / Aziz Amoozegar	120
Atterberg Limits / Thomas Baumgartl	171
Diffusivity: Measurement / Toru Nakajima	672
Microbial Biomass: Measurement / K.R. Islam and S.R. Wright	1429
Minirhizotron / Verónica Muñoz-Romero, Luis López-Bellido, F. Javier López-Bellido, and Rafael J. López-Bellido	1484
Pedometrics / Alex B. McBratney and Budiman Minasny	1677

Measurements, Testing, and Modeling (*cont'd.*)

Modeling

Fluid Flow: Modeling / John L. Nieber	930
Inorganic Carbon: Modeling / Leslie D. McFadden and Ronald G. Amundson	1213
Pedological Modeling / Ronald G. Amundson	1674
Soil Organic Matter (SOM): Modeling / Peter Smith	2159
Water Erosion: Empirical Models / John M. Laflen	2489
Water Erosion: Process-Based Modeling / Mark A. Nearing	2504
Water Management: Computer Modeling / Laj R. Ahuja and Liwang Ma	2510
Wind Erosion: Modeling / Lawrence J. Hagen	2632

Particle Measurements and Structure

Bulk Density / Kwong Yin Chan	258
Macroporosity / Daniel Gimenez and Daniel Hirmas	1388
Micromorphology and Soil Quality / Ahmet R. Mermut	1439
Particle Density / Keith R.J. Smettem	1652
Particle Packing / Satish C. Gupta and D.P. Thoma	1654
Particle Shape / Brian M. Schafer	1659
Particle Size / Hwat Bing So and Harold R. Geering	1661
Porosity: Pore Size Distribution / Keith C. Cameron and Graeme D. Buchan	1782
Structure / Eileen J. Kladviko	2207
Structure: Belowground Management / Ken A. Olsson and Bruce Cockroft	2209
Structure: Earthworms / Martin Shipitalo and Tayfun Korucu	2212
Structure: Pedological Concepts and Water Flow / Clinton C. Truman and Donald P. Franzmeier	2216
Structure: Plant Establishment / Douglas L. Karlen	2221
Structure: Roots / Alvin J.M. Smucker	2225
Surface Area: Specific / L.A. Graham Aylmore	2255

Quality

Quality / Ed G. Gregorich	1837
Quality Index: Soil / Toru Nakajima	1841
Quality: Assessment by Interpolation Techniques / Vincent Obade	1844
Quality: Critical Limits and Standardization / Martin R. Carter	1853
Quality: Indicators / Graham P. Sparling	1859
Quality: Productivity / Mike H. Beare	1862
Quality: Soil and Water / Todd Nissen and Michelle Wander	1866

Temperature

Heat and Water Movement / Gerald N. Flerchinger	1079
Heat Capacity / Surinder Kumar Jalota and B.S. Ghuman	1083
Heat Flux / Thomas J. Sauer	1086
Temperature Measurement / Kevin McInnes	2302

Physical Attributes

Albedo / Endre Dobos	89
Controlled Traffic / Randall C. Reeder	477
Eutrophication / Thomas G. Franti and Kyle D. Hoagland	855
Gas and Vapor Phase Transport / Dennis E. Rolston	986
Productivity: Natural and Anthropogenic Disturbances / Douglas G. Maynard and Charlotte E. Norris	1819

Scaling Effects / <i>Yakov A. Pachepsky, Walter J. Rawls, and John W. Crawford</i>	1976
Sediment: Influence on Aquatic Life / <i>Suzanne M. Gray</i>	1981
Seepage / <i>Patricia M. Gallagher</i>	1990
Shrinkage / <i>Des McGarry and Don F. Yule</i>	2008
Slaking, Dispersion, and Crust Formation / <i>Hwat Bing So</i>	2021
Surface Management / <i>Kwong Yin Chan</i>	2259
Turbations / <i>Brad D. Lee and Robert C. Graham</i>	2373
Vesicular Crusts / <i>Patrick Drohan</i>	2456
Weathering / <i>Dominique Righi</i>	2559

Processes

Aggregation

Aggregates: Tensile Strength / <i>Humberto Blanco-Canqui and Rattan Lal</i>	51
Aggregation / <i>Sjoerd W. Duiker</i>	55
Aggregation: Soil Organic Matter (SOM) and / <i>Cynthia A. Cambardella</i>	58
Aggregation: Structural Stability Measurement / <i>Edmund Perfect, Martín Díaz-Zorita, and John Grove</i>	61
Erosion: Aggregate Breakdown Mechanisms / <i>Yves Le Bissonnais</i>	757

Consolidation

Consolidation / <i>Tarunjit Singh Butalia</i>	474
--	-----

Degradation

Brick Making: Soil Degradation / <i>G.S. Dheri, Babu S. Brar, and Debankur Sanyal</i>	255
Degradation / <i>Rosa M. Poch Claret and José A. Martínez-Casasnovas</i>	548
Degradation: Biological / <i>Ibrahim Ortas</i>	553
Degradation: Chemical / <i>M. Rifat Derici</i>	558
Degradation: Critical Limits and Irreversible Degradation / <i>Anthony R. Dexter and Michael A. Zebisch</i>	561
Degradation: Economic Incentives and Investments / <i>Dennis Wichelns</i>	565
Degradation: Farm-Level Economic Implications / <i>Dennis Wichelns and Ellen Burnes</i>	568
Degradation: Food Aid Needs in Low-Income Countries / <i>Shahla Shapouri and Stacey Rosen</i>	571
Degradation: Food Security and Poverty / <i>Pierre Crosson</i>	574
Degradation: Greenhouse Effect / <i>Eddy De Pauw and Michael A. Zebisch</i>	578
Degradation: Mapping by Normalized Difference Vegetation Index (NDVI) / <i>Zhanquo Bai and David Dent</i>	581
Degradation: Off-Farm Economic Implications / <i>Dennis Wichelns and Ellen Burnes</i>	593
Degradation: Physical / <i>Michael A. Zebisch and Anthony R. Dexter</i>	596

Preface

Six important challenges facing humanity at the start of the twenty first century are: (1) a world population of 7.4 billion in 2016 projected to be 9.7 billion by 2050 and 11 billion by 2100; (2) a food-insecure population of 795 million in 2015 mostly in sub-Saharan Africa and South Asia; (3) severe and extreme forms of soil degradation affecting more than 300 million hectares (Mha) of agricultural lands, continuing unabated in developing countries where the resource-poor farmers cannot afford to invest in soil restoration; (4) an anthropogenic increase in atmospheric concentration of greenhouse gases such as CO₂, with current levels of 400 ppm in 2015 and increasing at the rate of 0.48% per year; CH₄ currently at 1.83 ppm and increasing at the rate of 0.49% per year; N₂O at 327 ppb and increasing at the rate of 0.34% per year; and atmospheric C pool at 840 Pg in 2016 and increasing at the rate of 4.4 Pg/yr; (5) a projected 40% decrease in the global per capita arable land area between 2000 and 2050; and (6) the threat of a decreasing, renewable fresh-water supply, affecting 2.3 billion people in 2000 and 3.5 billion by 2025. World soils, and their management, plays an important role in addressing these and other issues, especially those related to food security and climate change. Yes, soils matter.

Natural ecosystems have been drastically altered by anthropogenic perturbations due to increase in human population from about 0.2 billion in 1 A.D. to one billion in 1850, 6 billion in 1998, 7 billion in 2011, and 7.4 billion in 2016. Consequently, world forest resources have decreased from 55.3×10^6 Km² to 43.9×10^6 Km², world savannas from 33.4×10^6 Km² to 26.7×10^6 Km², and shrub land from 17.9×10^6 Km² to 15.9×10^6 Km² from prehistoric times to 1990. The present rate of tropical deforestation is about 7.8 million hectare per year with remaining forest area of <4 billion ha by 2015. Use of chemicals in agricultural ecosystems has increased drastically and, by 2012 chemical use included 125×10^6 Mg per year of N, 46×10^6 Mg per year for P and 25×10^6 Mg per year of potash. The annual need for N fertilizer is projected to be 135×10^6 Mg by the year 2020 and 236×10^6 Mg by 2050. Global water consumption has increased from 579 Km³ per year in 1900 to 3973 Km³ by 2000 of which 66% is for agriculture. Soil degradation affects 1.9 billion ha and is increasing due to anthropogenic activities and the projected global warming. Land degradation affects 24% of the global land area as of 2008. Therefore, need for understanding of soil processes is critical to restoring degraded/polluted soils, identifying sustainable systems of soil for food security and climate change.

The solution to these challenges lies in developing management strategies based on understanding the nature, properties, and dynamics of the life-support processes of the most basic of all natural resources ... the soil. This thin upper surface of the Earth's crust supports life in numerous ways—moderation of climate, filtration of chemicals, and the purification of water, detoxification of pollutants, restoration and resilience of ecosystems, and cycling of basic elements such as carbon, nitrogen, phosphorus, and sulfur. These life support functions of soil are precisely summed up in an old Chinese proverb that states “Man ... despite his artistic pretensions and many accomplishments ... owes his existence to a six-inch layer of topsoil and the fact that it rains.”

Traditionally, soil was regarded as a medium for plant growth, a repository of gene pool, an engineering foundation, an industrial raw material, and an archive of planetary history. However, to meet the challenges of the post-modern era of the twenty first century world soils must now also (1) maximize long-term productivity; (2) moderate moisture storage and distribution; (3) moderate climate and proxy for interpretation of past global changes and cultural heritage; (4) improve water resources; and (5) minimize environmental perturbation by functioning as a repository for waste disposal, an ameliorator of water quality through bioremediation, a sink for atmospheric carbon and other greenhouse gases, a component of biogeochemical cycles and other ecological processes, and a medium for immersing and loading infrastructure. To enhance soil's capacity to perform these functions, it is important to understand factors and processes affecting soil quality and health under growing and conflicting modes of land uses (among them agricultural, forestry, urban, industrial, military, aesthetic and cultural).

It is necessary that state-of-the-knowledge information about these complex attributes of soil and its multi-faceted functions of interest to humans is readily available to the scientific community, policy makers, and the public at large in an easily accessible compendium such as this Encyclopedia.

The *Third Edition* of the *Encyclopedia of Soil Science* has been compiled by over 500 experts in their fields. The *Third Edition* has been updated and includes more than 600 entries, compared with 458 in the *Second Edition* and 346 in the *First Edition*. These entries include discussions of important subjects prepared by soil scientists from around the world. The topics cover all branches of soil science, including pedology, mineralogy, physics, soil mechanics, hydrology, chemistry, biology, ecology and management, and restoration of problem or degraded soils, and address numerous challenges including soil structure, tillage methods, and mulch farming, irrigation, drainage and water table management, fertilizer and nutrient management, erosion control, climate change, soil carbon sequestration, and management of soil organic matter. Entries are alphabetically arranged within a theme, and a subject is included for easy access.

Preparation of this state-of-the-knowledge compendium on soil science has been made possible by hard work, vision, and commitment of hundreds of soil scientists from around the world who have contributed as members of the advisory board, as topic editors, or as authors. I thank all of them for their outstanding efforts to prepare the Third Edition in record time. I am thankful to all topic editors for identifying expert authors, for coordinating the writing with minimal duplication, and for carefully reviewing the manuscripts to ensure high quality. I also thank all the authors for their outstanding efforts in documenting and presenting, in a timely fashion, the scientific information supporting the current understanding of their field of specialization. Their efforts in the preparation of this volume provide an up-to-date information on the nature, properties, functions, and dynamics of soil.

Thanks are also due to the staff of Taylor and Francis for their efforts in making this information available to the world community. Ms. Sapna Maloor helped in the organization of the First Edition, Ms. Susan Lee in preparation of the Second Edition, Mr. Michael Powers and Mr. Daniel Vazquez and Ms. Claire Miller for the Third Edition. Their professionalism, commitment to excellence, and dedication to the mission is much appreciated. I also thank Mrs. Laura Conover of the Carbon Management and Sequestration Center at the Ohio State University for her efforts in handling the flow of manuscripts in the review process of the Third Edition. These efforts have produced a Third Edition of the *Encyclopedia of Soil Science* that contains information useful to meeting the challenges of the twenty first century and beyond.

Rattan Lal, Editor-in-Chief
Director, Carbon Management and Sequestration Center
The Ohio State University
Columbus, Ohio, U.S.A.

About the Editors

Dr. Rattan Lal

Rattan Lal, Ph.D., is a Distinguished University Professor of Soil Science and Director of the Carbon Management and Sequestration Center, The Ohio State University, and an Adjunct Professor of University of Iceland. With completion of education from Punjab Agricultural University, Ludhiana (B.Sc, 1963), Indian Agricultural Research Institute, New Delhi (M.Sc, 1965), and the Ohio State University, Columbus (Ph.D, 1968), he served as Sr. Research Fellow with the University of Sydney, Australia (1968–69), Soil Physicist at IITA, Ibadan, Nigeria (1969–87), and Professor of Soil Science at OSU (1987–to date). His current research focus is on climate-resilient agriculture, soil carbon sequestration, sustainable intensification, enhancing use efficiency of agroecosystems, and sustainable management of soil resources of the tropics. He is a fellow of the American Society of Agronomy (ASA, 1985), Soil Science Society of America (SSSA, 1986), Third World Academy of Sciences (1992), American Association for the Advancement of Sciences (1996), Soil and Water Conservation Society (SWCS, 1997), Indian Natl. Academy of Agricultural Sciences (1998), and Rothamsted, U.K. (2013). He

received the Hugh Hammond Bennett Award of the SWCS, 2005; Borlaug Award (2005), and Liebig Award (2006) of the International Union of Soil Sciences, M.S. Swaminathan Award (India) of 2009, and COMLAND Award (Germany, 2009). He received honorary degree of Doctor of Science from Punjab Agricultural University (2001), the Norwegian University of Life Sciences, Aas (2005), Alecu Russo Balti State University, Moldova (2010), and Technical University of Dresden Germany (2015) and cited in Thomas Reuters 2014 and 2015 list of World's Most Influential Scientific Minds. He was president of the World Association of the Soil and Water Conservation (1987–1990), the International Soil Tillage Research Organization (1988–91), the Soil Science Society of America (2005–2007), and is President of the International Union of Soil Sciences, Vienna, Austria (2017–2018). He was a member of the Federal Advisory Committee on National Assessment of Climate Change-NCADAC (2010–2014), member of the SERDP Scientific Advisory Board of the Department of Defense (2011–), Senior Science Advisor to the Global Soil Forum of IASS, Potsdam, Germany (2010–2012), member Steering Committee of the Global Soil Week, IASS, Potsdam, Germany (2012–), member Advisory Board of FACCE-JPI of the European Council (2013–2016), Chair Advisory Committee to UNU-FLORES, Dresden, Germany (2014–), and member of the Scientific Committee to implement “4 Pour Mille” program proposed at COP21 in Paris. Prof. Lal was a lead author of IPCC (1998–2000), and was awarded Nobel Peace Prize Certificate by IPCC in 2007, and Global Dry Land Champion of the United Nations Convention to Combat Desertification, Bonn, Germany in 2013. He has mentored 105 graduate students and 54 postdoctoral researchers, and hosted 152 visiting scholars from around the world. He has authored/co-authored more than 2023 research publications including 798 refereed journal articles and 436 book chapters, has written 19 and edited/co-edited 63 books.

Accounting: Emergy Analysis

Jay F. Martin

Department of Food, Agricultural, and Biological Engineering, Ohio State University, Columbus, Ohio, U.S.A.

D.R. Tilley

Department of Environmental Science and Technology, University of Maryland, College Park, Maryland, U.S.A.

Abstract

This entry explains the use of emergy analysis to evaluate systems and compare resource use, environmental loading, and sustainability. This method allows the free contributions of the environment to be compared directly with the purchased inputs from the economy. Results summarized from agriculture and forestry systems indicate that extensive amounts of indirect energy were dissipated to yield agricultural and forest products and that timber typically requires less indirect energy than crops. Timber production had higher average yields than agricultural crops, demonstrating that forests yield a greater amount of solar emergy per unit of economic input than crop systems. The average environmental loading of agricultural crops was greater than that of forests, revealing that crop production relies much more heavily on non-renewable and purchased inputs than forestry. Finally, the sustainability of forestry systems was much greater than crops, indicating that forests are more sustainable than cropland.

INTRODUCTION

The work of nature sustains the global life-support system for humans, contributes directly to human welfare, and is ultimately responsible for a large portion of the human economy. Quantifying the sustainability of human activities with an accounting system that values ecosystem work and the human economy on a comparable basis could improve environmental decision making. For example, modern agriculture in developed countries must supply more food, fiber, and fuels to an expanding world population under tightening environmental and energy constraints. Agriculture needs to reverse the trend of the 20th century when use of non-renewable resources increased faster than yields. Because systems like agriculture depend heavily on the unpaid work of nature, environmental accounting methods must be able to compare all the driving factors on a common basis. While the values of economic contributions are routinely quantified in economic analyses, such approaches often underestimate or fail to measure environmental contributions to production. If environmental inputs are not properly accounted for relative to economic inputs, optimum use of resources may not be achieved, and decisions will be based on incomplete information. In the 1970s, Odum published a pioneering, comprehensive look at how energy accounting could be applied to evaluate the

multiple inputs used to produce the world's food. Odum's novel approach went beyond an analysis of the energy inputs traditionally included—direct solar irradiance and fuel consumption—the contributions from the environment (e.g., dry air, water, and soil organic matter) and the economy (e.g., labor and services) as embodied solar energy (emergy in later nomenclature). Following his 1967 world food article, Odum focused on perfecting emergy accounting by formalizing its theoretical basis and conducting evaluations of systems around the world.^[1,2]

Emergy analysis is a form of energy analysis that quantifies values of natural and economic resources on a common basis to derive the contribution of nature to the human economy.^[1] Solar emergy is used to determine the contribution of environmental and human work to a system by transforming all inputs to the ultimate amount of solar energy required to produce each. Because of its ability to measure environmental and economic resources with a common metric, emergy analysis can quantify environmental sustainability. The solar emergy of products and services is calculated by multiplying energy by energy transformation ratios (transformities), mass by mass transformation ratios (specific emergy), and dollar by dollar transformation ratios (solar emergy $\$^{-1}$). In this entry, we introduce the concept of emergy accounting and review how it has been applied to assess environmental sustainability of agricultural and forested ecosystems.

DEFINITIONS OF TERMS AND INDICES

The following list defines key terms and indices used in energy analysis (Fig. 1). Emergy indices are calculated from aggregated data and used to quantify economic and environmental contributions to production, net process yield, environmental loading, and sustainability.^[1]

- **Emergy:** the available energy (exergy) of one kind used in transformations directly and indirectly to make a product or service. Emergy is measured in solar emjoules (sej). Sunlight, fuel, electricity, human service, and all resource flows are quantified as sej.
- **Transformity:** the amount of emergy required to produce a unit of available energy (exergy). For example, the solar transformity of wood is 20,000 sej J⁻¹ because 20,000 solar emjoules of environmental inputs were required to generate a joule of wood. The solar transformity of sunlight absorbed by the earth is defined as 1 sej J⁻¹. Transformities have been calculated for a wide variety of resources, commodities, and renewable energies.^[1,3-6]
- **Specific emergy:** emergy per mass, usually expressed as sej g⁻¹.
- **Emergy per unit money:** emergy supporting the generation of one unit of economic product (expressed as currency). Average emergy per money is calculated by dividing the total emergy use of an economy by its gross economic product (sej \$⁻¹).
- **Empower:** flow of emergy per time, usually expressed as solar empower (sej yr⁻¹).
- **Emergy yield ratio (EYR = Y/F):** emergy yield produced ($Y = R + N + F$) per unit of emergy contributed from the economy (F) (sej sej⁻¹).
- **Environmental loading ratio (ELR = (N + F)/R):** emergy contributed from non-renewable and economic sources per unit of emergy contributed from renewable

resources (sej sej⁻¹). It is an indicator of the pressure of agricultural systems on the environment and may be considered as a measure of ecosystem stress.

- **Emergy sustainability index (ESI = EYR/ELR):** the ratio of yield to environmental load, which measures system production relative to environmental pressure.
- **Emergy investment ratio (EIR = F/(N + R)):** emergy purchased and contributed from the economy (F) per unit of emergy contributed free from the environment whether renewable or non-renewable (R + N).

ENVIRONMENTAL DECISION MAKING WITH EMERGY

Emergy analysis begins with the construction of a systems diagram^[4,6] to define the boundary, identify resource inputs, and conceptualize relationships among components, inputs, and outputs. The emergy analysis table^[1] is constructed directly from the systems diagram using inflows and outflows crossing the system boundary as row headings. At first the annual amount of flow of each input and output is quantified in physical units (i.e., joules, grams, and dollars), then the annual solar emergy of each flow is calculated by multiplying the respective solar transformity, specific solar emergy, or solar emergy-to-money ratio. The flows are aggregated into categories of renewable resources (i.e., replenished within a year or less), non-renewable resources (i.e., replenished after multiple years), non-indigenous purchased resources (i.e., paid for and brought from outside system), and exports (or yield).

AGRICULTURAL PRODUCTION

As part of an emergy analysis of Italy, Ulgiati, Odum, and Bastianoni^[7] calculated emergy indices for several Italian crops and assessed the role of agriculture in Italy. The ELR for crop and livestock production in Italy was 2.5 and 3.3, respectively. Comparing these values with the Italian economy's mean, ELR of 9.5 indicated that Italian agriculture relied more heavily on natural environmental energy inputs than the economy as a whole. Table 1 compares the transformity and emergy indices for selected Italian crops. Almonds had the greatest transformity, indicating that more emergy was needed to produce one joule of almonds than any other crop. The relatively low ELR for almonds, wheat, rice, and forage indicated that these crops rely heavily on renewable emergy and lightly on purchased and non-renewable emergy. In contrast, sunflowers, oranges, and lemons required greater inputs of purchased and non-renewable emergy and had greater ELRs. Greater EYRs for crops such as almonds, wheat, rice, and forage indicated a greater yield for these crops

Fig. 1 Energy system diagram of the aggregated inputs (R, renewable; N, non-renewable; and F, purchased) to an evaluated system that produces a yield (Y) to the economy and generates sales revenue (S) that pays for purchased costs (C).

Table 1 Emergy indices for selected crops in Italian agriculture.

Crop	Solar transformity (1 E4 sej J ⁻¹)	ELR	EYR	ESI
Rice	7.78	2.86	1.38	0.48
Forage	8.00	1.45	1.76	1.21
Sugar beet	8.49	7.33	1.15	0.16
Corn	8.52	5.63	1.19	0.21
Wheat	15.90	3.38	1.32	0.39
Fruits	28.74	9.37	1.11	0.12
Vineyard	34.11	5.33	1.20	0.23
Oranges and lemons	38.17	11.82	1.09	0.09
Olive	53.03	4.40	1.24	0.28
Sunflower	79.12	27.78	1.04	0.04
Almonds	84.28	3.10	1.35	0.44

Source: From Ulgiati, Odum, et al.^[7]

relative to required economic investment. The ESI showed that almonds, wheat, rice, and forage crops were more sustainable than sunflower, orange, and lemon production.

Another study estimated that corn solar transformities declined from 8.41 to 5.11 E4 sej J⁻¹ in the United States from 1945 to 1994. This decline was due to more efficient use of inputs and less use of renewable resources. The ESI declined from 1.12 in 1945 to 0.34 in 1994, indicating that efficiency gains were overshadowed by increased non-renewable inputs. To increase sustainability of U.S. corn production, the authors suggested increasing production per emergy input, more reliance on local renewable resources, and less use of purchased inputs such as fertilizers and pesticides. Emergy was also used to evaluate cropping options in Southwestern Australia^[8] and to compare the sustainability of Swedish agriculture in 1927 and 1999.^[9]

FOREST PRODUCTION

Table 2 summarizes six emergy evaluations of timber yielding forests, including tropical, temperate, natural, and plantation systems operated since the 1970s under various harvest practices from clear-cutting to select-harvest. Timber production was the highest in the rain forest of Papua New Guinea (PNG) and the lowest in the ecologically managed Southern Appalachian forests of North Carolina. Environmental (i.e., renewable) inputs ranged from 605×10^{12} sej ha⁻¹ yr⁻¹ for the Jari, Brazil, forests to $26,074 \times 10^{12}$ sej ha⁻¹ yr⁻¹ for the primary growth PNG rain forest. One goal of timber yielding systems is to have a high return on investment, which is measured by the EYR. The sago palm system had the highest EYR, followed by the

Siris plantation of Puerto Rico, the tropical forest of Brazil, and the pine plantation of New Zealand. With the exception of sago palm, the EYR for timber production (1.5–2.8) was less than known EYRs of oil, coal, natural gas, and geothermal systems.^[1]

Another useful index for gauging the economic success of an operation that relies on natural resource inputs is the EIR. A process with a lower EIR than the larger scale economy that encompasses the process indicates a profitable investment, whereas an EIR higher than the mean economy EIR suggests that a greater proportion of resources must be diverted from the general economy to make the operation successful. For the timber yielding forests shown in Table 2, the sago palm system had the lowest EIR (0.15), while the PNG rain forest, which was a primary forest, had the highest EIR (1.63). Four of the evaluated forests had EIRs <1.0, showing that natural processes contributed more than the economy did.

The rain forest of PNG had the highest ELR due to the harvest of primary forests, while the majority of forests had an ELR below 1.0, which indicates that the relative load on the environment was small. The index of sustainability (ESI) indicated that the sago palm forest was the most sustainable. The Puerto Rico, North Carolina, Brazil, and New Zealand systems had ESIs of 5.0, 4.59, 3.68, and 3.07, respectively, which were all much greater than the least sustainable forest (PNG).

Ecological sources of renewable fuel, such as forests, most often have a lower EYR than non-renewable fuels, such as coal. This is partly because non-renewable resources are concentrated in space with a higher energy density and more accumulated solar emergy. Conversely, renewable fuel sources accumulate emergy slowly and are more dilute on the landscape. Odum found that the EYR of ecological sources of fuel, such as corn, sugarcane, pine plantations, and old-growth forests, was directly related to the replacement time of the biomass (p. 144).^[1] Corn with a replacement time of 1 year had an EYR of 1.1, while a 90-year-old Swedish spruce forest had an EYR of 4.1. The gathered evidence indicated that the EYR was linearly related to replacement time; each 50-year increase in replacement time increased the EYR by 1.75 units. Odum^[1] concluded that as the frequency of harvest diminished, the work of nature increased in proportion to the work of humans, resulting in a higher EYR.

CONCLUSION

Emergy analysis estimates the amount of solar energy required to operate a system for production, enumerating all flows of energy, material, and information in units of sej. The aggregation of inputs according to renewability and source location is used to create various indices. Emergy evaluations of agriculture and forest production systems

demonstrated that the multiple driving sources, with their various units of measure, could be aggregated to the amount of solar energy responsible for their existence. This allowed the free contributions of the environment to be compared directly with the purchased inputs from the economy. Past environmental work required to provide a modern flow of exergy embodied in agricultural products was reported as the solar transformity. Agricultural products had solar transformities ranging from 51,100sejJ⁻¹ for corn to 843,000sejJ⁻¹ for almonds, while timber was between 22,400 and 131,600sejJ⁻¹, indicating that extensive amounts of indirect energy were dissipated to yield agricultural and forest products and that timber typically requires less indirect energy than crops. Timber production had a higher average EYR (2.16 ± 0.55) than crop (1.26 ± 0.20) production, demonstrating that forests yield a greater amount of solar emergy per unit of

economic input than crop systems. The average ELR of crop fields (7.0) was greater than that of forests (0.50), revealing that crop production relies much more heavily on non-renewable and purchased inputs than forestry. The median ESI of forests (4.1) was much higher than crops (0.23), indicating that forests are over 10 times more sustainable than cropland.

Abstract

Acid mine drainage (AMD) consists of metal-laden solutions produced by the oxidative dissolution of iron sulfide minerals exposed to air, moisture, and acidophilic microbes during the mining of coal and metal deposits. The pH of AMD is usually in the range of 2–6, but mine-impacted waters at circumneutral pH (5–8) are also common. Mine drainage usually contains elevated concentrations of sulfate, iron, aluminum, and other potentially toxic metals leached from rock that hydrolyze and coprecipitate to form rust-colored encrustations or sediments. When AMD is discharged into surface waters or groundwaters, degradation of water quality, injury to aquatic life, and corrosion or encrustation of engineered structures can occur for substantial distances. Prevention and remediation strategies should consider the biogeochemical complexity of the system, the longevity of AMD pollution, the predictive power of geochemical modeling, and the full range of available field technologies for problem mitigation.

INTRODUCTION

Acid mine drainage (AMD) refers to metal-rich sulfuric acid (H_2SO_4) solutions released from mine tunnels, shafts, open pits, and waste rock piles. Similar solutions can be produced by the excavation of roadways through certain rocks, dredging of harbor sediments, or drainage of coastal wetlands.

Spoils and soils exposed to AMD tend to be sparsely vegetated and susceptible to erosion. When AMD enters waterways, increases in pH can result in the precipitation of metal hydroxide sediments, which smother aquatic habitats and clog the gills of fish and other aquatic life (Fig. 1). The corrosion of concrete and metal structures in contact with AMD, such as bridge pilings and pipes, is also greatly accelerated. Once initiated, AMD may persist for decades, making it a challenging problem to solve.

AMD results from the rapid oxidation of iron (Fe)-bearing sulfide minerals such as pyrite (cubic FeS_2), marcasite (orthorhombic FeS_2), pyrrhotite (Fe_{1-x}S , $x = 0$ to 0.2), chalcopyrite (CuFeS_2), and arsenopyrite (FeAsS). These minerals are commonly found in coal and ore deposits and are stable until exposed to oxygen and moisture. Sulfide oxidation produces H_2SO_4 , which can dissolve associated metals. This release of acid and metals can occur locally as a form of natural mineral weathering (Natural Acid Rock Drainage) but is exacerbated by mining because of the sudden, large-scale exposure of sulfides in unweathered rock to atmospheric conditions.

MINE DRAINAGE CHEMISTRY

AMD, in which mineral acidity exceeds alkalinity, typically contains elevated concentrations of sulfate (SO_4), Fe, manganese (Mn), aluminum (Al), and other solutes and may or may not have a low $\text{pH}^{[1]}$ (Table 1). AMD typically has pH from 2 to 6; however, sites, such as Iron Mountain, California, have produced extreme pH values as low as -3.6 .^[2,3] Neutral to alkaline mine drainage (NAMD), with pH from 5 to 8 and a surplus of alkalinity, is common in areas where the surrounding geologic units contain carbonate rocks to buffer acidity^[1,3,4] (Table 1). Because water discharged from mines generally is not at equilibrium with atmospheric conditions, the pH tends to be unstable—the hydrolysis of dissolved Fe, Al, and Mn can decrease the pH, while the outgassing of dissolved carbon dioxide (CO_2) can increase the pH. The “hot peroxide acidity” indicates the ultimate potential for the pH to be acidic or circumneutral and the amount of base required to neutralize the fully oxidized solution.^[4] Given sufficient time for equilibration with the atmosphere and oxidation and hydrolysis of dissolved Fe and Mn, AMD ultimately will have $\text{pH} \leq 4.5$, whereas NAMD ultimately will have $\text{pH} > 4.5$ (Table 1).

AMD forms by complex biogeochemical processes involving oxidation–reduction, hydrolysis, precipitation, and dissolution reactions as well as microbial catalysis.^[2] The entire sequence is commonly represented by Reaction 1, which describes the overall oxidation of pyrite by oxygen in the presence of water to form solid iron hydroxide

Fig. 1 (A) Discharge from the Old Forge Borehole (41.3591–75.75137), which drains a flooded underground coal mine in northeastern Pennsylvania, imparts a characteristic orange–brown turbidity to the Lackawanna River due to voluminous precipitates of iron hydroxide minerals. (B) Confluence of the Susquehanna River (at left) and Lackawanna River (at right) near Duryea, Pennsylvania (41.3412–75.7930), nearly 3 miles downstream from the Old Forge Borehole.

$[\text{Fe}(\text{OH})_3]$ and H_2SO_4 with the spontaneous release of energy as heat.

Chemolithotrophic microbes, described in more detail below, utilize the energy from the oxidation of Fe and sulfur (S).

Pyrite and related iron sulfide minerals contain both Fe and S in reduced oxidation states. When exposed to oxygen and water, the S moiety is oxidized first, releasing H_2SO_4 and Fe^{2+} to solution (Reaction 2). The rate of oxidation is dependent on environmental factors such as

temperature, pH, Eh, and relative humidity as well as mineral surface area and microbial catalysis.

Reaction 2 can be strictly abiotic or mediated by S-oxidizing bacteria.^[5] The Fe^{2+} is subsequently oxidized by oxygen, as described by Reaction 3.

If acidity generated by Reaction 2 exceeds the buffering capacity of the system, the pH eventually decreases. Below

Table 1 Summary of mine drainage chemistry for 140 abandoned coal mines in Pennsylvania, 1999.^[1]

	AMD (hot acidity ≥ 10 mg/L; N = 88)	NAMD (hot acidity < 10 mg/L; N = 52)
	Median (range)	Median (range)
pH, fresh (units)	4.1 (2.7 to 6.2)	6.2 (5.2 to 7.3)
pH, aged (units)	3.2 (2.2 to 4.6)	7.8 (4.7 to 8.6)
Alkalinity (mg/L as CaCO ₃)	0 (0 to 190)	125 (8 to 510)
Hot acidity (mg/L as CaCO ₃)	124 (10 to 1590)	-52 (-417 to 7.5)
Cl (mg/L)	4.9 (0.1 to 460)	20.5 (0.7 to 270)
SO ₄ (mg/L)	560 (34 to 2000)	475 (96 to 1400)
Ca (mg/L)	85 (3.3 to 410)	100 (11 to 320)
Mg (mg/L)	41 (3.6 to 210)	37 (8.5 to 140)
Na (mg/L)	6.9 (0.69 to 460)	63 (0.89 to 500)
K (mg/L)	2.6 (0.5 to 12)	3.2 (0.78 to 6.3)
Silica (mg/L)	20 (6.4 to 67)	15 (5.8 to 22)
Fe (mg/L)	41 (0.046 to 512)	23 (0.049 to 101)
Al (mg/L)	7.7 (0.014 to 108)	0.022 (0.007 to 1.5)
Mn (mg/L)	3.4 (0.39 to 74)	1.5 (0.02 to 9.2)
As (mg/L)	0.0010 (< 0.00003 to 0.064)	0.0052 (< 0.00003 to 0.015)
Cu (mg/L)	0.0039 (0.00045 to 0.19)	0.0008 (0.0004 to 0.017)
Ni (mg/L)	0.145 (0.02 to 3.2)	0.0225 (0.0026 to 0.12)
Pb (mg/L)	0.00067 (< 0.00001 to 0.011)	< 0.00001 (< 0.00001 to 0.00068)
Zn (mg/L)	0.27 (0.011 to 10)	0.0088 (0.0006 to 0.25)

pH 3, Fe³⁺ solubility increases and a second mechanism of pyrite oxidation becomes important (Reaction 4).

In this case, pyrite is oxidized by Fe³⁺ resulting in the generation of even greater acidity than when oxygen is the primary oxidant. Pyrite decomposition is thus controlled by the rate at which Fe²⁺ is converted to Fe³⁺ at low pH.^[6] At pH < 5 , Fe²⁺ oxidation by Reaction 3 is very slow unless catalyzed by populations of acidophilic, Fe-oxidizing bacteria^[6,7] that oxidize Fe²⁺ as a means of generating energy. In doing so, they supply soluble Fe³⁺ at a rate equal to or slightly greater than the rate of pyrite oxidation by Fe³⁺. Pyrite oxidation then regenerates Fe²⁺ (Reaction 4) creating a cyclic situation that leads to vigorous acidification of mine drainage water.

MINE DRAINAGE MINERALOGY

Sulfide mineral oxidation typically takes place in humid air above the groundwater table or at the land surface, where reactants are present and variably soluble products including secondary sulfate minerals may accumulate. Commonly observed secondary sulfates associated with weathered pyrite include melanterite (FeSO₄ • 7H₂O), rozenite (FeSO₄ • 4H₂O), szomolnokite (FeSO₄ • H₂O),

copiapite (Fe^{II}Fe^{III}₄(SO₄)₆(OH)₂ • 20H₂O), and coquimbite (Fe₂(SO₄)₃ • 9H₂O).^[3,8,9] Such secondary SO₄ minerals can also form by the evaporation of AMD during dry periods. Dissolution of these relatively soluble “acid sulfate” minerals by infiltrating water or runoff can result in the rapid release of “stored acidity.”^[3,9] For example, H₂SO₄ is a product of the dissolution of coquimbite (Reaction 5).

The Fe³⁺ released by dissolution of such SO₄²⁻ minerals may interact with pyrite (Reaction 4) or hydrolyze and precipitate as a variety of insoluble Fe minerals, generally represented as [Fe(OH)₃] (Reaction 6).

These rust-colored (yellow-to-red-to-brown) solids can impart turbidity to the water or coat streambeds and aquatic plants and, thus, are often the most obvious indicators of mine drainage contamination. The actual mineralogy of the precipitates is determined by solution parameters such as pH, SO₄, and metal concentration and can vary both spatially and temporally. Some of the most common mine drainage minerals are goethite (α-FeOOH), ferrihydrite (Fe₅HO₈ • 4H₂O), schwertmannite [Fe₈O₈(OH)₆SO₄], and jarosite [(H₃O, K, Na)Fe₃(OH)₆(SO₄)₂].^[10] Goethite is a crystalline oxyhydroxide that is relatively stable over

a wide pH range and may represent a final transformation product of other mine drainage minerals.^[10,11] Ferrihydrite is a poorly crystalline ferric oxide that forms in higher pH (> 6.5) environments. Schwertmannite is commonly found in drainage waters with pH ranging from 2.8 to 4.5 and with moderate to high SO₄ contents. Schwertmannite may be the dominant phase controlling Fe and trace metal concentrations in most AMD.^[12] Jarosite group minerals form in more extreme environments, often with pH < 3, very high SO₄ concentrations, and in the presence of appropriate cations such as sodium (Na) and potassium (K).^[10]

MINE DRAINAGE MICROBIOLOGY

The most studied bacterial species in mine drainage systems belong to the genus *Acidithiobacillus* (formerly *Thiobacillus*).^[13] Species such as *Acidithiobacillus thiooxidans* and *Acidithiobacillus ferrooxidans* are important in S and Fe oxidation in acid drainage; however, many other microorganisms, such as *Leptospirillum* species, may also be involved.^[3] Bacteria have been found in close association with pyrite grains and may play a direct role in mineral oxidation,^[5] but they most likely function indirectly through oxidation of dissolved Fe²⁺ as described previously. In low pH systems (< 3), *A. ferrooxidans* can increase the rate of Fe oxidation as much as five orders of magnitude relative to strictly abiotic rates.^[6,7]

Fe-oxidizing bacteria are chemolithotrophic, meaning they oxidize inorganic compounds, such as Fe²⁺, to generate energy and use CO₂ as a source of carbon. Fe oxidation, however, is a very low energy yielding process compared to heterotrophic processes. It has been estimated that the oxidation of 90.1 moles of Fe²⁺ is required to assimilate 1 mole of C into biomass.^[14] Thus, large amounts of Fe²⁺ must be oxidized to achieve even modest growth.

In addition to mediating Fe oxidation, bacteria may play an additional role in mineral formation. Bacterial cells in mine drainage systems are often partially encrusted with mineral precipitates.^[15] Bacterial cell walls provide reactive sites for the sorption of metal cations, which can accumulate and subsequently develop into precipitates using the bacterial surface (living or dead) as a template.^[16]

ENVIRONMENTAL IMPACTS OF MINE DRAINAGE

AMD from mine openings, such as tunnels or shafts, or from mine spoil can impact aquatic environments substantial distances downstream. Chemical precipitates can smother streambed habitats, obstruct water flow, dramatically increase turbidity, and ruin stream aesthetics. Dissolved metals and acidity can also be toxic to plants and animals.

Besides Fe, dissolved Al is common in AMD. The primary source of Al is the acid dissolution of aluminosilicates found in soil, spoils, tailings deposits, and gangue material.^[10] At moderate concentrations (<1 mg/L), Al can be toxic

to plants, and colloidal Al precipitates can clog or irritate the gills of fish and other aquatic organisms causing suffocation. Al occurs as a dissolved species at low pH but rapidly hydrolyzes at about pH 5 to form “amorphous” feldsparite [Al₄(SO₄)(OH)₁₀ • 4H₂O] or gibbsite [Al(OH)₃].^[3,10] Al precipitates are white in color but are readily masked by associated Fe compounds.

Elevated concentrations of trace elements such as arsenic (As), copper (Cu), nickel (Ni), lead (Pb), and zinc (Zn) may be released during the oxidation of sulfide minerals and be present in AMD and NAMD solutions (Table 1). These elements can play a role in mineralization processes by forming coprecipitates with iron sulfate and hydroxide minerals^[9,17] but occur primarily as sorbed species with the hydroxides.^[8,12] Mine drainage precipitates can retain both anions and cations, depending on pH. While coprecipitation and sorption function to immobilize trace elements by removing dissolved ions from solution, this effect may not be permanent. Dissolution of precipitates and shifts in pH can result in the release of sorbed species, providing a latent source of pollution.^[18]

DEALING WITH MINE DRAINAGE

Successful control of mine drainage usually involves varying degrees of prevention and treatment.

Prevention

Prevention techniques include sealing mine shafts to prevent discharge, burying or submerging spoil piles to reduce contact by oxygen, reining and recycling of waste materials to eliminate the sulfide minerals, and the addition of bactericides to limit catalysis by Fe-oxidizing bacteria. These techniques often have limited success. Sealing of mines is extremely difficult due to fractures and the permeability of surrounding rocks. Covering spoil with soil material can decrease the degree of sulfide oxidation by limiting exposure to oxygen, but establishment of a vegetative cover is necessary to prevent erosion from reexposing the spoil. Submerging mine waste in water may be effective where oxidation has not initiated; however, previously formed oxidation products can be dissolved with acidity, metals, and SO₄ released to solution (Reaction 5). Reining and recycling may not be economically viable. Inhibition of Fe-oxidizing bacteria with bactericides can decrease sulfide mineral oxidation and reduce metal mobility; however, reapplication is necessary and adequate distribution to all affected areas is difficult. In addition, target bacteria may develop resistance and beneficial bacteria may be harmed.^[5]

Treatment

The traditional approach to treatment of AMD involves neutralization of acidity by the addition of alkaline chemical agents such as caustic soda (NaOH) or hydrated

lime [Ca(OH)₂]. This method is effective in rapidly increasing pH and precipitating dissolved metals; however, it requires continuous oversight and produces large amounts of metal-rich sludge that require disposal. Alternative remediation strategies focus on low-maintenance treatment methods. For example, diverting AMD through limestone drains coupled with settling ponds or aerobic wetlands have shown some promise as passive remediation technologies.^[19] In these systems, drainage is channeled through either oxic or anoxic limestone substrates to neutralize active acidity. Dissolved metals are then allowed to hydrolyze and precipitate in ponds or wetland cells. A major difficulty is the coating of limestone surfaces by precipitates of Fe and Al that may eventually obstruct flow. When drainage is naturally net alkaline, engineered aeration systems can be effective in promoting CO₂ outgassing, which increases pH and the rate of abiotic Fe(II) oxidation, with the rapid removal of dissolved Fe by mineral precipitation.^[20]

Compost wetlands are designed to stimulate the development of anaerobic microbial populations, particularly SO₄-reducing bacteria. The bacteria use the compost as an organic substrate and remove SO₄ from solution either by converting it to hydrogen sulfide (H₂S), which is lost to the atmosphere, or by forming insoluble iron sulfides (Reactions 7 and 8).

Bicarbonate is formed as a by-product of SO₄ reduction and functions to buffer acidity. These systems have also shown limited success in the field because the SO₄ removal rates are usually low (<10%), and pH often remains unchanged or decreases within the system.^[11] Nevertheless, bioreactors involving SO₄ reduction can be effective for removing potentially toxic trace elements such as Zn and Cu that form sulfide precipitates.

Acid Rain: Nitrogen Deposition

George F. Vance

Department of Renewable Resources, University of Wyoming, Laramie, Wyoming, U.S.A.

Abstract

Air pollution has occurred naturally since the formation of the earth's atmosphere; however, the industrial era has resulted in human activities greatly contributing to global atmospheric pollution. One of the more highly publicized and controversial aspects of atmospheric pollution is that of acidic deposition. Acidic materials can be transported long distances, some as much as hundreds of kilometers. Acidic deposition can impact buildings, sculptures, and monuments that are constructed using weatherable materials like limestone, marble, bronze, and galvanized steel. While acid soil conditions are known to influence the growth of plants, agricultural impacts related to acidic deposition are of less concern due to the buffering capacity of these types of ecosystems. When acidic substances are deposited in natural ecosystems, a number of adverse environmental effects are believed to occur, including damage to vegetation, particularly forests, and changes in soil and surface water chemistry.

INTRODUCTION

Air pollution has occurred naturally since the formation of the earth's atmosphere; however, the industrial era has resulted in human activities greatly contributing to global atmospheric pollution.^[1,2] One of the more highly publicized and controversial aspects of atmospheric pollution is that of acidic deposition. Acidic deposition includes rainfall, acidic fogs, mists, snowmelt, gases, and dry particulate matter.^[3] The primary origin of acidic deposition is the emission of sulfur dioxide (SO₂) and nitrogen oxides (NO_x) from fossil fuel combustion; electric power-generating plants contribute approximately two-thirds of the SO₂ emissions and one-third of the NO_x emissions.^[4]

Acidic materials can be transported long distances, some as much as hundreds of kilometers. For example, 30%–40% of the sulfur (S) deposition in the northeastern United States originates in industrial Midwestern U.S. states.^[5] After years of debate, United States and Canada have agreed to develop strategies that reduce acidic compounds originating from their countries.^[5,6] In Europe, the small size of many countries means that emissions in one industrialized area can readily affect forests, lakes, and cities in another country. For example, approximately 17% of the acidic deposition falling on Norway originated in Britain, and 20% in Sweden came from eastern Europe.^[5]

The U.S. Environmental Protection Agency National Acid Precipitation Assessment Program (NAPAP) conducted intensive research during the 1980s and 1990s that resulted in the “Acidic Deposition: State of the Science and Technology” that was mandated by the Acid Precipitation Act of 1980.^[6] NAPAP Reports to Congress have been developed in accordance with the 1990 amendment to the 1970 Clean Air Act and present the expected benefits of the

Acid Deposition Control Program.^[6,7] Mandates include an annual 10 million ton or approximately 40% reduction in point-source SO₂ emissions below 1980 levels, with national emissions limit caps of 8.95 million tons from electric utility and 5.6 million tons from point-source industrial emissions. A reduction in NO_x of about 2 million tons from 1980 levels has also been set as a goal; however, while NO_x has been on the decline since 1980, projections estimate a rise in NO_x emissions after the year 2000. In 1980, the U.S. levels of SO₂ and NO_x emissions were 25.7 and 23.0 million tons, respectively.

Acidic deposition can impact buildings, sculptures, and monuments that are constructed using weatherable materials like limestone, marble, bronze, and galvanized steel.^[7,8] While acid soil conditions are known to influence the growth of plants, agricultural impacts related to acidic deposition are of less concern due to the buffering capacity of these types of ecosystems.^[5] When acidic substances are deposited in natural ecosystems, a number of adverse environmental effects are believed to occur, including damage to vegetation, particularly forests, and changes in soil and surface water chemistry.^[9,10]

SOURCES AND DISTRIBUTION

Typical sources of acidic deposition include coal- and oil-burning electric power plants, automobiles, and large industrial operations (e.g., smelters). Once S and nitrogen (N) gases enter the earth's atmosphere, they react very rapidly with moisture in the air to form sulfuric acid (H₂SO₄) and nitric acid (HNO₃).^[2,3] The pH of natural rainfall in equilibrium with atmospheric carbon dioxide (CO₂) is about 5.6; however, the pH of rainfall is less than 4.5 in

many industrialized areas. The nature of acidic deposition is controlled largely by the geographic distribution of the sources of SO_2 and NO_x (Fig. 1). In the Midwestern and northeastern United States, H_2SO_4 is the main source of acidity in precipitation because of the coal-burning electric utilities.^[2] In the western United States, HNO_3 is of more concern because utilities and industries burn coal with low S contents and populated areas are high sources of NO_x .^[2]

Emissions of SO_2 and NO_x increased in the 20th century due to the accelerated industrialization in the developed countries and antiquated processing practices in some undeveloped countries. However, there is some uncertainty as to the actual means by which acidic deposition affects our environment^[11,12] (<http://nadp.sws.uiuc.edu/isopleths/maps1999/>). Chemical and biological evidence, however, indicates that atmospheric deposition of H_2SO_4 caused some New England lakes to decrease in alkalinity.^[13,14] Many scientists are reluctant to overgeneralize cause and effect relationships in an extremely complex environmental problem. However, the National Acid Deposition Assessment Program has concluded that there were definite

consequences due to acidic deposition that warrant remediation.^[6,7] Since 1995, when the 1990 Clean Air Act Amendment's Title IV reduction in acidic deposition was implemented, SO_2 and NO_x emissions have, respectively, decreased and remained constant during the late 1990s.^[4]

Both H_2SO_4 and HNO_3 are important components of acidic deposition, with volatile organic compounds and inorganic carbon also components of acidic deposition-related emissions. Pure water has a pH of 7.0, natural rainfall about 5.6, and severely acidic deposition less than 4.0. Uncontaminated rainwater has a pH of 5.6 due to CO_2 chemistry and the formation of carbonic acid (H_2CO_3). The pH of most soils ranges from 3.0 to 8.0.^[2] When acids are added to soils or waters, the decrease in pH that occurs depends greatly on the system's buffering capacity, the ability of a system to maintain its present pH by neutralizing added acidity. Clays, organic matter, oxides of aluminum (Al) and iron (Fe), and calcium (Ca) and magnesium (Mg) carbonates (limestones) are the components responsible for pH buffering in most soils. Acidic deposition, therefore, will have a greater impact on sandy, low organic

Fig. 1 Acidic deposition across the United States during 1999.

Source: From the National Atmospheric Deposition Program (NRSP-3)/National Trends Network.^[11]

matter soils than on those higher in clay, organic matter, and carbonates. In freshwaters, the primary buffering mechanism is the reaction of dissolved bicarbonate ions (HCO_3^-) with hydrogen ion (H^+) according to the following equation:

HUMAN HEALTH EFFECTS

Few direct human health problems have been attributed to acidic deposition. Long-term exposure to acidic deposition precursor pollutants such as ozone and NO_x , which are respiratory irritants, can cause pulmonary edema.^[5,6] SO_2 is also a known respiratory irritant, but is generally absorbed high in the respiratory tract.

Indirect human health effects due to acidic deposition are more important. Concerns center around contaminated drinking water supplies and consumption of fish that contain potential toxic metal levels. With increasing acidity (e.g., lower pH levels), metals such as mercury, aluminum, cadmium, lead, zinc, and copper become more bioavailable.^[2] The greatest human health impact is due to the consumption of fish that bioaccumulate mercury; freshwater pike and trout have been shown to contain the highest average concentrations of mercury.^[5,15] Therefore, the most susceptible individuals are those who live in an industrial area, have respiratory problems, drink water from a cistern, and consume a significant amount of freshwater fish.

A long-term urban concern is the possible impact of acidic deposition on surface-derived drinking water. Many municipalities make extensive use of lead and copper piping, which raises the question concerning human health effects related to the slow dissolution of some metals (lead, copper, zinc) from older plumbing materials when exposed to more acidic waters. Although metal toxicities due to acidic deposition impacts on drinking waters are rare, reductions in S and N fine particles expected by 2010 based on Clean Air Act Amendments resulted in annual public health benefits valued at \$50 billion with reduced mortality, hospital admissions, and emergency room visits.^[16]

STRUCTURAL IMPACTS

Different types of materials and cultural resources can be impacted by air pollutants. Although the actual corrosion rates for most metals have decreased since the 1930s, data from three U.S. sites indicate that acidic deposition may account for 31–78% of the dissolution of galvanized steel and copper.^[7,8] (<http://www.nnmc.noaa.gov/CENR/NAPAP/>). In urban or industrial settings, increases in atmospheric acidity can dissolve carbonates (e.g., limestone and marble) in buildings and other structures. Deterioration of stone

products by acidic deposition is caused by: 1) erosion and dissolution of materials and surface details; 2) alterations (blackening of stone surfaces); and 3) spalling (cracking and spalling of stone surfaces due to accumulations of alternation crusts.^[8] Painted surfaces can be discolored or etched, and there may also be degradation of organic binders in paints.^[8]

ECOSYSTEM IMPACTS

It is important to examine the nature of acidity in soil, vegetation, and aquatic environments. Damage from acidification is often not directly due to the presence of excessive H^+ , but is caused by changes in other elements. Examples include increased solubilization of metal ions such as Al^{3+} and some trace elements (e.g., Mn^{2+} and Pb^{2+}) that can be toxic to plants and animals, more rapid losses of basic cations (e.g., Ca^{2+} and Mg^{2+}), and the creation of unfavorable soil and aquatic environments for different fauna and flora.

Soils

Soil acidification is a natural process that occurs when precipitation exceeds evapotranspiration.^[2] “Natural” rainfall is acidic (pH of ~5.6) and continuously adds a weak acid (H_2CO_3) to soils. This acidification results in a gradual leaching of basic cations (Ca^{2+} and Mg^{2+}) from the uppermost soil horizons, leaving Al^{3+} as the dominant cation that can react with water to produce H^+ . Most of the acidity in soils with pH between 4.0 and 7.5 is due to the hydrolysis of Al^{3+} .^[17,18] (<http://www.epa.gov/airmarkets/acidrain/effects/index.html>). Other acidifying processes include plant and microbial respiration that produces CO_2 , mineralization and nitrification of organic N, and the oxidation of iron disulfide (FeS_2) in soils disturbed by mining or drainage.^[2] In extremely acidic soils (pH < 4.0), strong acids such as H_2SO_4 are a major component.

The degree of accelerated acidification depends on both the buffering capacity of the soil and the use of the soil. Many of the areas subjected to the greatest amount of acidic deposition are also areas where considerable natural acidification occurs.^[19] Forested soils in the northeastern United States are developed on highly acidic, sandy parent materials that have undergone tremendous changes in land use in the past 200 years. However, clear-cutting and burning by the first European settlers have been almost completely reversed, and many areas are now totally reforested.^[5] Soil organic matter that accumulated over time represents a natural source of acidity and buffering. Similarly, greater leaching or depletion of basic cations by plant uptake in increasingly reforested areas balances the significant inputs of these same cations in precipitation.^[20,21] Acidic deposition affects forest soils more than agricultural or urban soils because the latter are routinely limed to neutralize acidity.

Although it is possible to lime forest soils, which is done frequently in some European countries, the logistics and cost often preclude this except in areas severely impacted by acidic deposition.^[5]

Excessively acidic soils are undesirable for several reasons. Direct phytotoxicity from soluble Al^{3+} or Mn^{2+} can occur and seriously injure plant roots, reduce plant growth, and increase plant susceptibility to pathogens.^[21]

The relationship between Al^{3+} toxicity and soil pH is complicated by the fact that in certain situations organic matter can form complexes with Al^{3+} that reduce its harmful effects on plants.^[18] Acid soils are usually less fertile because of a lack of important basic cations such as potassium ion (K^+), Ca^{2+} , and Mg^{2+} . Leguminous plants may fix less N_2 under very acidic conditions due to reduced rhizobial activity and greater soil adsorption of molybdenum by clays and Al and Fe oxides.^[2] Mineralization of N, phosphorus, and S can also be reduced because of the lower metabolic activity of bacteria. Many plants and microorganisms have adapted to very acidic conditions (e.g., pH < 5.0). Examples include ornamentals such as azaleas and rhododendrons and food crops such as cassava, tea, blueberries, and potatoes.^[5,22] In fact, considerable efforts in plant breeding and biotechnology are directed toward developing Al- and manganese-tolerant plants that can survive in highly acidic soils.

Agricultural Ecosystems

Acidic deposition contains N and S that are important plant nutrients. Therefore, foliar applications of acidic deposition at critical growth stages can be beneficial to plant development and reproduction. Generally, controlled experiments require the simulated acid rain to have pH of 3.5 or less in order to produce injury to certain plants.^[22] The amount of acidity needed to damage some plants is 100 times greater than natural rainfall. Crops that respond negatively in simulated acid rain studies include garden beets, broccoli, carrots, mustard greens, radishes, and pinto beans, with different effects for some cultivars. Positive responses to acid rain have been identified with alfalfa, tomato, green pepper, strawberry, corn, lettuce, and some pasture grass crops.

Agricultural lands are maintained at pH levels that are optimal for crop production. In most cases, the ideal pH is around pH 6.0–7.0; however, pH levels of organic soils are usually maintained at closer to pH 5.0. Because agricultural soils are generally well buffered, the amount of acidity derived from atmospheric inputs is not sufficient to significantly alter the overall soil pH.^[2] N and S soil inputs from acidic deposition are beneficial, and with the reduction in S atmospheric levels mandated by 1990 amendments to the Clean Air Act, the S fertilizer market has grown. The amount of N added to agricultural ecosystems as acidic deposition is rather insignificant in relation to the 100–300 kg N/ha/yr required for most agricultural crops.

Forest Ecosystems

Perhaps the most publicized issue related to acidic deposition has been widespread forest decline; e.g., in Europe estimates suggest that as much as 35% of all forests have been affected.^[23] Similarly, in the United States many important forest ranges such as the Adirondacks of New York, the Green Mountains of Vermont, and the Great Smoky Mountains in North Carolina have experienced sustained decreases in tree growth for several decades.^[6] Conclusive evidence that forest decline or dieback is caused solely by acidic deposition is lacking and complicated by interactions with other environmental or biotic factors. However, NAPAP research^[6] has confirmed that acidic deposition has contributed to a decline in high-elevation red spruce in the northeastern United States. In addition, N saturation of forest ecosystems from atmospheric N deposition is believed to result in increased plant growth, which in turn increases water and nutrient use followed by deficiencies that can cause chlorosis and premature needle-drop as well as increased leaching of base cations from the soil.^[24]

Acidic deposition on leaves may enter directly through plant stomates.^[1,22] If the deposition is sufficiently acidic (pH ~3.0), damage can also occur to the waxy cuticle, increasing the potential for direct injury of exposed leaf mesophyll cells. Foliar lesions are one of the most common symptoms. Gaseous compounds such as SO_2 and sulfur trioxide present in acidic mists or fogs can also enter leaves through the stomates, form H_2SO_4 upon reaction with H_2O in the cytoplasm, and disrupt many metabolic processes. Leaf and needle necrosis occurs when plants are exposed to high levels of SO_2 gas, possibly due to collapsed epidermal cells, eroded cuticles, loss of chloroplast integrity and decreased chlorophyll content, loosening of fibers in cell walls and reduced cell membrane integrity, and changes in osmotic potential that cause a decrease in cell turgor.

Root diseases may also increase in excessively acidic soils. In addition to the damages caused by the exposure to H_2SO_4 and HNO_3 , roots can be directly injured or their growth rates impaired by increased concentrations of soluble Al^{3+} and Mn^{2+} in the rhizosphere^[2,25] (<http://nadp.sws.uiuc.edu>). Changes in the amount and composition of these exudates can then alter the activity and population diversity of soilborne pathogens. The general tendency associated with increased root exudation is an enhancement in microbial populations due to an additional supply of carbon (energy). Chronic acidification can also alter nutrient availability and uptake patterns.^[8,22]

Long-term studies in New England suggest that acidic deposition has caused significant plant and soil leaching of base cations,^[1,21] resulting in decreased growth of red spruce trees in the White Mountains.^[6] With reduction in about 80% of the airborne base cations, mainly Ca^{2+} but also Mg^{2+} , from 1950 levels, researchers suggest that forest growth has slowed because soils are not capable of

weathering at a rate that can replenish essential nutrients. In Germany, acidic deposition was implicated in the loss of soil Mg^{2+} as an accompanying cation associated with the downward leaching of SO_4^{2-} , which ultimately resulted in forest decline.^[2] Several European countries have used helicopters to fertilize and lime forests.

Aquatic Ecosystems

Ecological damage to aquatic systems has occurred from acidic deposition. As with forests, a number of interrelated factors associated with acidic deposition are responsible for undesirable changes. Acidification of aquatic ecosystems is not new. Studies of lake sediments suggest that increased acidification began in the mid-1800s, although the process has clearly accelerated since the 1940s.^[15] Studies indicate that there is significant S mineralization in forest soils impacted by acidic deposition and that the SO_4^{2-} levels in adjacent streams remain high, even though there has been a decrease in the amount of atmospheric S deposition.^[24]

Geology, soil properties, and land use are the main determinants of the effect of acidic deposition on aquatic chemistry and biota. Lakes and streams located in areas with calcareous geology resist acidification more than those in granitic and gneiss materials.^[16] Soils developed from calcareous parent materials are generally deeper and more buffered than thin, acidic soils common to granitic areas.^[2] Land management decisions also affect freshwater acidity. Forested watersheds tend to contribute more acidity than those dominated by meadows, pastures, and agronomic ecosystems.^[8,14,20] Trees and other vegetation in forests are known to “scavenge” acidic compounds in fogs, mists, and atmospheric particulates. These acidic compounds are later deposited in forest soils when rainfall leaches forest vegetation surfaces. Rainfall below forest canopies (e.g., throughfall) is usually more acidic than ambient precipitation. Silvicultural operations that disturb soils in forests can increase acidity by stimulating the oxidization of organic N and S and reduced S compounds such as FeS_2 .^[2]

A number of ecological problems arise when aquatic ecosystems are acidified below pH 5.0 and particularly below pH 4.0. Decreases in biodiversity and primary productivity of phytoplankton, zooplankton, and benthic invertebrates commonly occur.^[15,16] Decreased rates of biological decomposition of organic matter have occasionally been reported, which can then lead to a reduced supply of nutrients.^[20] Microbial communities may also change, with fungi predominating over bacteria. Proposed mechanisms to explain these ecological changes center around physiological stresses caused by the exposure of biota to higher concentrations of Al^{3+} , Mn^{2+} , and H^+ and lower amounts of available Ca^{2+} .^[15] One specific mechanism suggested involves the disruption of ion uptake and the ability of aquatic plants to regulate sodium ion (Na^+), K^+ , and Ca^{2+} export and import from cells.

Acidic deposition is associated with declining aquatic vertebrate populations in acidified lakes and, under conditions of extreme acidity, of fish kills. In general, if the water pH remains above 5.0, few problems are observed; from pH 4.0 to 5.0, many fish are affected, and below pH 3.5, few fish can survive.^[23] The major cause of fish kill is due to the direct toxic effect of Al^{3+} , which interferes with the role Ca^{2+} plays in maintaining gill permeability and respiration. Ca has been shown to mitigate the effects of Al^{3+} , but in many acidic lakes, the Ca^{2+} levels are inadequate to overcome Al^{3+} toxicity. Low pH values also disrupt the Na^+ status of blood plasma in fish. Under very acidic conditions, H^+ influx into gill membrane cells both stimulates excessive efflux of Na^+ and reduces influx of Na^+ into the cells. Excessive loss of Na^+ can cause mortality. Other indirect effects include reduced rates of reproduction, high rates of mortality early in life or in reproductive phases of adults, and migration of adults away from acidic areas.^[16] Amphibians are affected in much the same manner as fish, although they are somewhat less sensitive to Al^{3+} toxicity. Birds and small mammals often have lower populations and lower reproductive rates in areas adjacent to acidified aquatic ecosystems. This may be due to a shortage of food due to smaller fish and insect populations or due to physiological stresses caused by consuming organisms with high Al^{3+} concentrations.

REDUCING ACIDIC DEPOSITION EFFECTS

Damage caused by acidic deposition will be difficult and extremely expensive to correct, which will depend on our ability to reduce S and N emissions; e.g., society may have to burn less fossil fuel, use cleaner energy sources, and/or design more efficient “scrubbers” to reduce S and N gas entering our atmosphere. Despite the firm conviction of most nations to reduce acidic deposition, it appears that the staggering costs of such actions will delay implementation of this approach for many years. The 1990 amendments to the Clean Air Act are expected to reduce acid-producing air pollutants from electric power plants. The 1990 amendments established emission allowances based on a utilities’ historical fuel use and SO_2 emissions, with each allowance representing 1 ton of SO_2 that can be bought, sold, or banked for future use.^[4,6,7] (<http://www.nnmc.noaa.gov/CENR/NAPAP/>). Short-term remedial actions for acidic deposition are available and have been successful in some ecosystems. Liming of lakes and some forests (also fertilization with trace elements and Mg^{2+}) has been practiced in European countries for over 50 years.^[16,23] Hundreds of Swedish and Norwegian lakes have been successfully limed in the past years. Lakes with short mean residence times for water retention may need annual or biannual liming; others may need to be limed every 5–10 years. Because vegetation in some forested ecosystems has adapted to acidic soils, liming (or overliming) may result in an unpredictable and undesirable redistribution of plant species.

Acid Sulfate Soils

Delvin S. Fanning

*Department of Environmental Science and Technology, University of Maryland,
College Park, Maryland, U.S.A.*

Abstract

Acid sulfate soils are a special group of mineral soils. They either have ultralow pH in near surface horizons or they have the potential to become ultra acid upon the exposure of sulfide minerals that they contain to oxidizing conditions, or they have been ultra acid in the past as evidenced by the presence in their profiles of the yellow iron hydroxysulfate mineral, jarosite, or other special characteristics. Sulfuric acid formed from the oxidation of iron sulfides, in most cases from the mineral pyrite, is the acid of concern with these soils and with waters that emanate from them.

INTRODUCTION

Pons^[1] reported that acid sulfate soils have been known for ages, which began to receive scientific attention in the 18th century when Linnaeus recognized them in the Netherlands with terms such as *argilla vitriolacea*, meaning “clay with sulfuric acid.” Terms such as “kattekleigronden” in Dutch, “cat clay soils” in English, and “Maibolt” in German, which are used to imply hayfields affected by an evil spirit or “Gifterde” for poison earth, were applied to these soils to connote the mysterious and evil circumstances surrounding the difficulty in producing crops on them. The term “acid sulfate soils” is of more modern usage. It has gained popularity with the four international acid sulfate soils symposia^[2–5] that have been held under the sponsorship of the International Land Reclamation Institute (ILRI), Wageningen, the Netherlands, and other organizations, and usage of the term is apparent in many other publications^[6–8] on these soils.

DEFINITION AND MAIN KINDS

In the broad sense, acid sulfate soils include all soils in which sulfuric acid may be produced, is being produced, or has been produced in amounts that have a lasting effect on main soil characteristics.^[1,9] This definition includes potential, active, and postactive acid sulfate soils, which are broad genetic kinds as described in the following three paragraphs.

Potential acid sulfate soils are anaerobic soils, commonly occurring in, or at one time formed in, coastal (tidal) sedimentary environments affected by sulfidization. Potential acid sulfate soils contain sulfide minerals at such levels in near surface horizons/layers that they are expected to generate, upon exposure to oxidizing conditions, sufficient sulfuric acid to drive the pH of these horizons/layers to

ultralow levels. Under these conditions, most plants would be unable to grow on the soils, and an active acid sulfate soil would then be recognized.

Active acid sulfate soils form where sulfide minerals (most typically iron sulfides and the mineral pyrite) have oxidized in near surface horizons and formed enough sulfuric acid, with insufficient neutralization, in order to make the pH drop to ultralow levels. Most commonly the pH, as measured in water, is 3.5 or less, such that a “sulfuric horizon,” as defined later, is recognized. Some soil scientists would only require the pH to be 4.0 or below to recognize the active stage.

In postactive acid sulfate soils, weathering and pedogenesis have proceeded beyond the active stage to where sulfide minerals are no longer present in surface soil horizons, and the pH in these horizons has risen to levels above that which would cause them to be recognized as sulfuric horizons.

A simpler definition of acid sulfate^[8] is simply that they are soils that contain iron sulfides. This definition calls attention to the minerals that cause acid sulfate soils to become acid; however, it neglects to consider that the degree of acidity of the soils depends on the balance between the acid-forming substances (mainly iron sulfides) and the substances (minerals) that neutralize acidity, most commonly calcium carbonate minerals. This simpler definition also does not recognize the genetic distinction among the potential, active, and postactive stages of development of acid sulfate soils.

CLASSIFICATION IN SOIL TAXONOMY

Potential, active, and early postactive acid sulfate soils receive special recognition in *Soil Taxonomy*.^[10–12] The taxonomic definition of “sulfidic materials” also permits the recognition of these acid-forming materials, regardless

of their depth in the soil–geologic column. This is useful for their recognition in construction activities such as mining, highway construction, and dredging operations, which can bring active acid sulfate soils into existence by exposing (to oxidation) sulfidic materials that previously occurred deep in the column or under deep water.

Diagnostic Characteristics

Sulfidic Materials

Soil Taxonomy^[10] gives the following definition:

Sulfidic materials contain oxidizable sulfur compounds. They are mineral or organic soil materials that have a pH value of more than 3.5 and that, if incubated as a layer 1 cm thick under moist aerobic conditions (field capacity) at room temperature, show a drop in pH of 0.5 or more units to a pH value of 4.0 or less (1 : 1 by weight in water or in a minimum of water to permit measurement) within 8 weeks.

Sulfidic materials were defined to permit the recognition of soil materials that lead to the formation of active acid sulfate soils if exposed to aerobic conditions at land surfaces. Sulfidic materials, when they are mineral soil materials, typically have Munsell color chromas ≤ 1 and values ≤ 4 .^[12]

Sulfuric Horizon

Following is the definition of sulfuric horizon as given in *Soil Taxonomy*.^[10,11]

The sulfuric (*L. sulfur*) horizon is 15 cm or more thick and is composed of either mineral or organic soil material that has a pH value of 3.5 or less (1 : 1 in water or in a minimum of water to permit measurement) and shows evidence that the low pH value is caused by sulfuric acid. The evidence is *one or more* of the following: (a) Jarosite concentrations; (b) directly underlying sulfidic materials; or (c) 0.05 percent or more water-soluble sulfate.

The definition of the sulfuric horizon permits the recognition of active acid sulfate soils and soil materials affected by active sulfuricization.

Classes

Potential and active acid sulfate soils are classified in *Soil Taxonomy* in the orders of Entisols, Inceptisols, and Histosols. Within these orders, acid sulfate soils are recognized at the great group and subgroup levels, which are intermediate categories—third and fourth in level from the top (order) level of the six categories of *Soil Taxonomy*. Mineral potential acid sulfate soils that have sulfidic materials within 50 cm of their surfaces without an overlying sulfuric horizon

are classified in the great group of Sulfaquepts. Organic potential acid sulfate soils that have sulfidic materials within 100 cm of their surfaces without a sulfuric horizon within 50 cm of their surface are classified as either Sulphemists or Sulfisapristis.

Active acid sulfate soils are recognized in *Soil Taxonomy* as soils that have a sulfuric horizon with its upper boundary within 50 cm of the soil surface. Those that are mineral soils are classified as either Sulfaquepts or Sulfudepts, whereas those that are organic soils are classified as either Sulfohemists or Sulfosapristis. Most of these soils would be wet soils, belonging to an Aqu-suborder or are organic soils that formed under wet conditions, those with the “ist” stem; however, the Sulfudepts are better drained and would be the active acid sulfate soils of upland exposures, such as on mined land spoils that were not reclaimed properly.

Postactive acid sulfate soils are recognized in *Soil Taxonomy* only if they are early postactive. For example, Sulfuric Endoaquepts are Endoaquepts that have either sulfidic materials or a sulfuric horizon or “a horizon 15 cm or more thick that has all of the characteristics of a sulfuric horizon, except that it has a pH between 3.5 and 4.0” within 150 cm of the mineral soil surface.^[10,11] Many other soils beyond those recognized by *Soil Taxonomy* are considered to be postactive, such as certain Alfisols and Ultisols in Texas^[13] and certain Ultisols in Maryland.^[14] It is important to recognize such soils because they do usually contain sulfidic materials at a depth that could give rise to new active acid sulfate soils if unearthed by land-moving operations and to understand better the morphology, genesis, and other aspects of these soils.^[15]

CLASSIFICATION IN OTHER SYSTEMS

Dent^[6] has presented the ILRI system for the classification of acid sulfate soils, which considers acidity and potential acidity, salinity, soil composition and texture, degree of physical ripening, and profile form (the depth zone at which various properties occur). The Food and Agriculture Organization (FAO) of the United Nations groups potential and active acid sulfate soils together in thionic classes for purposes of showing these soils on the FAO/United Nations Educational, Scientific and Cultural Organization soil map of the world.^[16] Thionic Fluvisols, thionic Gleysols, and thionic Histosols are recognized.^[7]

CONCLUSION

Acid sulfate soils are a special group of mineral soils, although some organic soils are included. They either have ultralow pH (3.5, measured in water) in near surface horizons (active acid sulfate soils) or they have the potential to become ultra acid upon the exposure of sulfide minerals that they contain to oxidizing conditions (potential acid

sulfate soils), or they have been ultra acid in the past as evidenced by the presence in their profiles of the yellow iron hydroxysulfate mineral jarosite or other special characteristics (postactive acid sulfate soils). Sulfuric acid formed from the oxidation of iron sulfides, in most cases from the mineral pyrite, FeS_2 , is the acid of concern with these soils and with waters that emanate from them. Special characteristics, sulfidic materials and the sulfuric horizon, have been defined in *Soil Taxonomy* to enable the recognition and classification of these soils. The soils receive special classification in other classification systems as well.

Acid Sulfate Soils: Distribution and Extent

Wim Andriessse

Green World Research, Wageningen University, Wageningen, the Netherlands

M.E.F. van Mensvoort

Laboratory of Soil Science and Geology, Wageningen University and Research Center, Wageningen, the Netherlands

Abstract

This entry discusses the global and regional distribution of acid sulfate soils and their extent. Acid sulfate soils, in spite of their notoriety, do not cover large acreages of land worldwide. They are important, however, in terms of the specific management they require in order to avoid catastrophic acidification upon drainage and in terms of their specific occurrence that is genetically linked to coastal areas. Mostly, these coastal lands comprise densely populated areas of high economic importance.

INTRODUCTION

International scientific attention to acid sulfate soils has been channeled through four international symposia^[1–4] under the aegis of the International Institute for Land Reclamation and Improvement (ILRI) in Wageningen, The Netherlands. This entry discusses the global and regional distribution of acid sulfate soils and their extent. Acid sulfate soils, in spite of their notoriety, do not cover large acreages of land worldwide. They are important, however, in terms of the specific management they require in order to avoid catastrophic acidification upon drainage and in terms of their specific occurrence that is genetically linked to coastal areas.^[5,6] Mostly, and this is particularly the case in South and Southeast Asia, West, and Southern Africa, and along the South American and Australian coastlines, these coastal lands comprise densely populated areas of high economic importance. Here, alternative land for food production and cash crops is scarce. See the related entries *Acid Sulfate Soils* (p. 17–19), *Acid Sulfate Soils: Formation* (p. 26–30), *Acid Sulfate Soils: Management* (p. 31–35), and *Acid Sulfate Soils: Problems* (p. 36–39) for more information.^[6,7]

GLOBAL DISTRIBUTION AND EXTENT

Estimates of the total area of potential and actual acid sulfate soils in the world are in the order of 12–13 millionha (Table 1). Approximately, 10 millionha are known to occur in tropical regions.^[5,8–10] Over much larger areas (potential) acid sulfate soil materials occur under thick covers of peat (mainly in Indonesia and Malaysia) or under non-pyritic alluvial sediments. In addition, Pleistocene, Tertiary,

or still-older pyritic sediments, often originating from tidal environments, occur in inland positions. Examples have been found in Canada and the United States (many authors), the Soviet Union, Uganda, Great Britain, Denmark, Zimbabwe, Germany, and The Netherlands.^[11–17]

In the FAO–UNESCO Legend for the Soil Map of the World^[18] acid sulfate soils, both potential and actual are called Thionic Fluvisols. Beek et al.,^[5] ISRIC,^[9] and Dent^[6] describe the world distribution of Thionic Fluvisols based on the work of Kawalec^[8] and FAO.^[18] Large extensions occur in South and Southeast Asia, in West Africa, and along the northeastern coast of South America (the Guyana's, the Orinoco, and Amazon deltas). Smaller areas are found in coastal regions of Eastern and Southern Africa, particularly in Madagascar, along the Australian coastline and in the Caribbean. In Southeast Asia, the bulk of the acid sulfate soils (approximately 5 millionha) is found in Indonesia, Thailand, and Vietnam. Millions of hectares of peat land in Indonesia (Kalimantan and Sumatra) are underlain by potentially acid sediments. These peat lands do not qualify as Thionic Fluvisols properly, and their extent has not been included in the tables. It should be noted that, after a major revision, the FAO Legend recognizes Thionic Gleysols and Thionic Histosols as well as Thionic Fluvisols.^[19]

Table 1 has been compiled on the basis of data from the FAO–UNESCO Soil Map of the World.^[18] In Table 2, these data have been updated, based on an extensive literature survey^[10] by Langenhoff in 1986. In the last column of Table 2, the authors have again revised the acreages of potential and actual acid sulfate soils based on new information and on expert knowledge, including an accuracy assessment of the available information. Their new estimate amounts to a world total of over 17 millionha. This higher figure is mainly due to the “discovery” of acid sulfate soils in Australia since the 1980s.

Table 1 Regional distribution of acid sulfate soils.

Region	Area (million ha)	Area (million ha) per length of growing period (day)			
		<90	90–180	180–300	>300

REGIONAL DISTRIBUTION

At landscape level, saline and brackish-water tidal swamps and marshes form the ecological environment for the formation of potential acid sulfate soils. The prevailing dense vegetation fuels the process of pyrite formation, the tidal cycle brings in sediment, renews the supply of dissolved sulfate, and removes soluble by-products.^[6,21] Slight differences within this general setting may cause important spatial variations in potential acidity, even over small distances.

According to Pons et al.,^[22,23] regional soil patterns are related to changes in relative sea level and the rate of sedimentation, as well as to changes in climate, hydrology, and chemical composition of floodwaters. In general, where sedimentation keeps pace with the rising sea level, broad and stable tidal swamp zones build up in which thick layers of sulfidic materials accumulate. If sea levels rise slowly and heavy sedimentation continues, coastal swamp formation extends rapidly in seaward direction and sediments are

generally thinner and have lower pyrite contents. This is mainly caused by the unfavorable conditions for development of dense mangrove and reed vegetation. Favorable conditions for the formation of pyritic sediments as

outlined above occur in coastal deltas, sheltered estuaries, and coastlines protected by offshore islands and bars (e.g., the lagoons along the West African coastline between Côte d'Ivoire and Nigeria).

Abstract

Soils containing sulfide minerals that have not yet been oxidized through acid sulfate weathering are referred to as potential acid sulfate soils (SS). The processes involved in the formation and accumulation of sulfide minerals in soils leading to the formation of potential acid SS will be discussed first. Subsequently, processes related to the oxidation of sulfides in the formation of active acid SS will be examined.

INTRODUCTION

The extent of acid sulfate soils (SS) worldwide has been estimated to be approximately 12–15 Mha. (For details, see the entry *Acid Sulfate Soils: Distribution and Extent*, p. 20–25.)

POTENTIAL ACID (SS) AND SULFIDE MINERAL FORMATION—SULFIDIZATION

Biogeochemistry of Sulfide Mineral Formation

Several factors are required for sulfate reduction. These include a source of sulfate, a source of oxidizable carbon, reducing conditions, and the presence of sulfate-reducing bacteria.^[1] Any of these components could theoretically limit sulfate reduction. In saturated soil or sedimentary environments where the required factors are present, heterotrophic microbes utilize sulfate as an electron acceptor that becomes reduced to sulfide according to Eq. 1.

Sulfate

Provided that the other required factors are met, the quantity of sulfate may limit the rate of sulfate reduction. Goldhaber and Kaplan^[2] reported sulfate reduction to be independent of concentration when sulfate levels are above 10 mM (320 mg/l). Work by Haering,^[3] in Chesapeake Bay, indicated that sulfate levels may begin to limit sulfur (S)

accumulation in marsh soils when levels drop below 1 mM (32 mg/l). Some degree of sulfate reduction will continue as long as sulfate is present at minimal levels ($> 5\text{--}20 \mu\text{M}$, 0.16–0.6 mg/l).^[4] Because sulfate-reducing bacteria are better able to compete for electron-donating substrates than are methane-generating bacteria, methanogenesis is of minimal significance so long as sulfate levels are above 0.03–0.4 mM.^[5] Therefore, sulfate reduction dominates in brackish systems. In freshwater, sulfate reduction may become overshadowed by methanogenesis as sulfate is depleted.

Oxidizable organic carbon

The oxidation of organic matter provides the energy microorganisms need to facilitate sulfate reduction. Plant materials rich in labile components are more easily decomposed than humified soil organic matter or peat. In sediments low in organic matter, sulfate reduction may be limited by the paucity of oxidizable carbon. This can be demonstrated in thin sections from mineral horizons in tidal marsh soils where iron sulfide (FeS) minerals have accumulated in pores occupied by decaying plant roots (Fig. 1). The intimate association of pyrite (FeS₂) with the decomposing organic minerals, and its near absence from the surrounding soil matrix, suggests that organic matter is limiting the formation of sulfide.^[6]

Reducing/saturated conditions

Because diffusion of gases through saturated soils and sediments is very slow, oxygen becomes depleted

Fig. 1 Micrograph of a thin section from the mineral (Cg) horizon of a tidal marsh soil illustrating accumulation of FeS_2 framboids in the channel occupied by decaying plant roots. Plane polarized light; frame length 1.2 mm.

under saturated conditions and microbes that utilize other electron acceptors become active. Nitrate, Mn(IV) , and Fe(III) are so utilized as the environment becomes progressively reduced (Fig. 2). If the conditions permit the entry of oxygen, then redox potentials may never become sufficiently low to foster sulfate reduction. More typically, diffusion of oxygen into a saturated soil or sediment is sufficiently slow, and if other necessary factors are present, sulfate reduction will occur. Fig. 2 illustrates that pH, as well as E_h , must be specified in assessing S phase equilibria; e.g., as the pH increases from 5 to 7, the minimum E_h at which sulfate reduction

Fig. 2 pe-pH diagram illustrating the location of stability fields for redox-sensitive components. The sulfate-sulfide lines (green) is based on a (SO_4^{2-}) concentration of 10 mM and a pH_2S of 0.001 atm. (Blue line separates the pyrolucite- Mn^{2+} stability fields; red line separates the goethite- Fe^{2+} stability fields.)

is expected decreases from approximately -50 to -200 (based on a SO_4^{2-} concentration of 10 mM and a pH_2S of 0.0001 atm).

Sulfate-reducing bacteria

Some 15 genera of bacteria have been recognized as sulfate reducers including *Desulfovibrio*, *Desulfotomaculum*, and *Desulfobacter*.^[7,8] These organisms thrive under strongly reducing conditions, but many are able to persist in aerobic conditions for significant periods of time. Thus, if the other factors necessary for sulfate reduction are present, sulfate-reducing bacteria will also become active.

As with most heterotrophic bacteria, rates of sulfate reduction are temperature dependent. Optimum temperature for most sulfate reducers is $30\text{--}40^\circ\text{C}$,^[7] and the rate of sulfate reduction generally increases with temperature across this range. Some groups of sulfate reducers are thermophilic and can function at temperature up to 85°C . Thus, in tropical coastal wetlands, sulfate reduction occurs all year round. In higher latitudes, where soil and sediment temperatures may approach biological zero, rates may become very slow during winter.

Reactive Fe

Once formed, sulfide is available to form a variety of minerals provided that there is adequate reactive iron (Fe) present. Most of the Fe enters coastal environments as Fe oxides sorbed to the surface of clay and silt particles. When Fe oxides in the sediments and marsh soils become reduced to Fe(II) , they can form FeS minerals. While monosulfide species may form first (Eq. 2), and minerals such as greigite (Fe_3S_4) may persist in recent sediments, disulfide forms such as FeS_2 are energetically more stable and will form at the expense of the monosulfides.

Mechanisms for FeS_2 formation may follow several possible pathways including 1) reaction of monosulfide with polysulfide; 2) partial oxidation of monosulfide; and 3) reaction of monosulfides with H_2S ^[9] (Eq. 3). Sulfide itself has the ability to reduce Fe(III) to Fe(II) on the surface of Fe oxides.^[10] FeS_2 can occur either as small ($<2\text{ }\mu\text{m}$) individual crystals or as spherical clusters of crystals called framboids. In low organic mineral sediments, reactive Fe is usually present in excess, resulting in a low degree of pyritization.^[11] However, in organic-rich soils, Fe may limit the accumulation of sulfide minerals, and the degree of pyritization is generally high. This has been demonstrated experimentally in salt marsh Histosols.^[12]

Environments of Sulfide Formation and Accumulation

It is clear that in environments that provide a source of oxidizable carbon and sulfate and that are sufficiently saturated to enhance reducing conditions, sulfate-reducing bacteria will generate sulfide. If reactive Fe is present, then solid-phase ferrous minerals will accumulate. This process of *sulfidization*^[13] is shown schematically in Fig. 3. The obvious settings for these processes are coastal marine and brackish environments, where sulfate is abundant. Under permanently submersed conditions, detrital carbon is added by flora and fauna to the sediment. In shallow water settings (<3 m) where various pedogenic processes are at work, these accumulated sediments have been recognized as subaqueous soils^[14] and are classified to reflect the sulfide components.

The soils of coastal marshes (in temperate environments) and mangroves (in tropical settings) also are ideal for sulfide formation and accumulation. The high primary productivity of these ecosystems (up to $3 \text{ kg m}^{-2} \text{ yr}^{-1}$ in marshes and up to $5 \text{ kg m}^{-2} \text{ yr}^{-1}$ in mangroves)^[15] makes these an exceptionally good environment for sulfate reduction. Such soils may contain up to 20–30 g/kg of S in FeS_2 , and estimates of S in FeS_2 accumulation rates in estuarine marshes are as high as $7 \text{ g m}^{-2} \text{ yr}^{-1}$.^[16]

Sulfate reduction can occur in other settings, so long as a source of sulfate is available. While generally small, atmospheric deposition of sulfate may be enough to induce sulfate reduction in the sediments of some interior freshwater lakes. Sulfate reduction has also been documented in prairie potholes where sulfate has apparently been contributed by the weathering of S-bearing shales.^[17]

FORMATION OF ACTIVE ACID SS—SULFURICIZATION

Chemistry of Sulfide Oxidation

Sulfides begin to oxidize once they are exposed to more oxidizing conditions. This occurs most often as a result of such human activities as drainage or dredging of sulfide-bearing soils or sediments, or the mining of sulfide-bearing coal, but may also occur due to tectonic uplift or oceanic regression. Under humid or moist aerobic conditions, sedimentary sulfide minerals can oxidize chemically,^[18] but this is a slow process, probably due to particular rate-limiting reactions. Various microorganisms are adapted to oxidize sulfides either directly through S transformations or by facilitating (catalyzing) such rate-limiting reactions as the oxidation of Fe(II) to Fe(III) .^[19] While there are many possible intermediate reactions in the oxidation of FeS_2 , the overall reaction is summarized in Eq. 4. One mole of FeS_2 eventually yields two moles of sulfuric acid and a mole of Fe hydroxide.

The oxidation of FeS_2 proceeds along two fronts (Fig. 4). First, the S is oxidized (through intermediates) to sulfate yielding sulfuric acid and the remaining Fe(II) . The generated Fe(II) sulfate salts are very soluble and potentially mobile. Second, Fe(II) is oxidized to Fe(III) , which when hydrolyzed produces additional acid. At high pH, the oxidation of sulfide is accomplished with oxygen, but under low pH conditions sulfide is oxidized by Fe(III) . Microorganisms such as *Thiobacillus ferrooxidans* facilitate this

reaction by oxidizing Fe(II) to Fe(III). For more details, refer to the entry *Acid Mine Drainage*, p. 6–10.

Other Aspects of Sulfurification and Properties of Acid SS

Sulfurification is the overall process by which sulfide-bearing minerals are oxidized, minerals are weathered by the sulfuric acid produced, and new mineral phases are formed from the dissolution products.^[13] (See also the entry *Acid Mine Drainage*, p. 6–10.) When CaCO_3 minerals are present, the sulfuric acid reacts with them to form the mineral gypsum, according to Eq. 5.

As long as sufficient CaCO_3 is present, the pH is prevented from becoming very low and the soil does not become acid.

When insufficient acid-neutralizing minerals are present, the oxidation of FeS_2 in soils will lower the pH. The pH of active SS commonly drops to below four and in extreme can go below two. As Fe is oxidized and hydrolyzed, various Fe minerals form in the soil including ferrihydrite, schwertmannite, and goethite. If the soil pH falls below four while maintaining an oxidizing environment ($E_h > 400$ mV), then the mineral jarosite ($\text{KFe}_3(\text{SO}_4)_2(\text{OH})_6$) can form.^[21] Because ($\text{KFe}_3(\text{SO}_4)_2(\text{OH})_6$) forms under conditions of high E_h and very low pH, which can only develop from the generation of sulfuric acid, it is considered a diagnostic mineral for acid SS (See also the entry *Sulfate and Sulfide Minerals*, p. 2238.).

($\text{KFe}_3(\text{SO}_4)_2(\text{OH})_6$) has been reported in soils, which are not extremely acid and which may even contain carbonates.^[22] These are interpreted to be “postactive” acid SS, meaning that earlier in their pedogenic history, they had undergone acid sulfate weathering. Subsequently, the soil pH has risen due to weathering of silicate minerals or addition of eolian carbonates. Because the redox potential has remained strongly oxidized, the ($\text{KFe}_3(\text{SO}_4)_2(\text{OH})_6$) has persisted as a metastable species. A review of acid SS including a discussion of the modeling of associated processes has been published.^[23]

Abstract

The issue of acid sulfate soils (ASSs) is of global extent, and their management must encompass all of those landscapes containing sulfurous material, both soft sediments and hard rocks, located on coasts and inland of land masses because there has been a marked shift in understanding the links that various disciplines share about the geochemical sulfur cycle and aspects of its management. Thus, soil scientists are joining mining geologists and engineers, and others in sharing experience and potential techniques for better managing these sulfurous landscapes. Nevertheless, the emergence of the “pyrite-heave” problem with construction, particularly in Canada and Ireland, shows that there must be greater linkages; education and communication between such disciplines; and politicians, regulators, and all stakeholders must be involved for better ASS management. There are three fundamental questions underlying the use of ASS sites and landscapes. Firstly, how best to use the existing environment productively while minimizing sulfide mineral oxidation. Secondly, how to sustainably neutralize any existing or newly created acidity within a particular land use. Thirdly, how to eliminate or minimize downstream impacts from ASS drainage waters. Such an holistic approach might best be achieved by an acceptance by all stakeholders of a sense of environmental stewardship for environmental management.

INTRODUCTION

Acid sulfate soils (ASSs) is the name given to all those soils or unconsolidated sediments that contain reduced sulfur minerals and compounds that have been or can be oxidized and thereby produce acidity.^[1] Thus, we are interested in the existence and behavior of the iron disulfide mineral, pyrite.^[2] In the previous two editions of this encyclopedia,^[3] we discussed some of the problems and relationships between ASSs and acid rock drainage (ARD). In much of the initial research about ASS, the emphasis was on coastal locations in Holocene-age materials (<10,000 yr). However, it is clear that much older, inland materials must also be considered.^[4] Subsequently, we expanded on this widened theme and described management approaches that were appropriate to minimize the problems associated with these sulfurous materials. It is appropriate to also include some of the problems associated with what might be best termed “construction and development” involving sulfurous materials because we have become aware of this very large and important issue and options that have been or are being adopted for their best management. It seems that as the global population increases, there is an increasing need for production of food and development of infrastructure to

accommodate the larger population, and this development must be completed at a larger scale, more rapidly, and relatively more cheaply. The management options available for particular sites depend upon the specific problem, its scale, and the particular economics of the situation. Nevertheless, there are three fundamental questions underlying the development of a particular ASS site or landscape. Firstly, how best to productively use the existing environment while minimizing any additional sulfide mineral oxidation. Secondly, how to effectively neutralize any existing or new acidity created during the development. Thirdly, how to eliminate or minimize downstream environmental impacts from ASS drainage waters, such as acidification, deoxygenation, or release of metals and nutrients. Best management must therefore address these questions.

EMERGING PROBLEMS FOR MANAGEMENT

The agronomic problems of ASS have been recognized for centuries in Europe and management techniques developed, particularly following the large-scale polder developments in The Netherlands. The experiences from there were transferred to developments in more tropical

environments, and the initial international symposia, after 1973, emphasizing these interests were organized by International Institute for Land Reclamation and Improvement (ILRI) from Wageningen. Australia had very limited scientific interest in ASS until the 1987 flood on the Tweed River where the entire 23 km of the estuary became clarified and sterilized of fish and benthic organisms. The cause and source of this problem were identified (as from the floodplain ASS) by the astute observations of the local government entomologist, Clive Easton,^[5] who had for many years been manipulating floodplain agricultural drains so as to better control problem mosquito populations. We consider Easton's paper seminal to the subsequent development of Australian scientific, environmental, governmental, and public interest in ASS. This interest has developed in Australia so that ASSs have become an essential management requirement regulated by most levels of government across the nation, but this has been generally a cooperative learning process.^[6] This development has been greatly advanced by much research publication, personnel training and education, and National ASS Conferences in Australia. Beginning with the 4th International ASS Symposium organized by ILRI in Ho Chi Minh City, Vietnam, in 1992, the environmental and engineering aspects of ASS and ARD have become the leading interests of subsequent international ASS/ARD symposia and the ASS Working Group discussions at the International Soil Science Symposia.

Events of acidification and deoxygenation of ASS drainage and receiving waters are seen around the world that lead to major fish kills but also to the increased concentration of dissolved iron at micromolar concentrations, and the associated deleterious phytoplankton blooms have been linked to ASS discharges.^[7] Discharge of metals in agricultural ASS drainage systems of Finland (the largest area of ASS in Europe) greatly exceed that from industrial effluents, and much research and development has been undertaken to reduce this impact.^[8,9] Emissions from ASS of toxic and greenhouse gases have also been reported.^[10,11] Hydrological changes to ASS landscapes, such as the increase in evapotranspiration and lowering of the water table, can allow oxidation of sulfides in the sediment and the associated acidification of contained pore water. Such changes can be by either natural causes or by imposed drainage systems. Our major research site at McLeods Ck is an ASS Tweed River estuarine floodplain, almost entirely under sugarcane cultivation. Robert Quirk has developed and implemented a wide range of ASS management options so as to minimize acidity export problems but also to increase sugarcane productivity.^[12,13] We have found it difficult to distinguish between natural and artificial drainage impacts on sulfidic oxidation, but the latter provides the conduit by which acidity from whatever cause is transferred to receiving waters and therefore requires careful management.^[14] In some locations, such as in the Mekong Delta of Vietnam, increased abstraction of water flow in the

upstream nations along the Mekong River has led to increased ASS problems and tidal incursions into distributary channels and canals draining the Delta. Thus, floodgates on all distributary channels and canals have been installed to stop this incursion with an intended increase in rice production across the Delta. Unfortunately, many of the local farmers depend upon seasonal brackish water incursions to enable the better cash crop from shrimp production. This dichotomy of purpose was explained to us as “those imposing the floodgates view seawater as their enemy, these farmers see seawater as their friend.”

In southeastern Australia, the severe drought from 2005 to about 2009 markedly reduced delivery of discharge to, and therefore desiccation in, the outflow lakes and other wetlands along the lower Murray River. This caused oxidation of the sulfide minerals contained in the previously saturated sediments, and severe acidification and environmental problems ensued.^[15] Subsequent reflooding with freshwater did not immediately reverse these problems.^[16] While natural climatic variation was the main cause here, the imposition of flow restrictions and abstraction to enable irrigation in upstream reaches of the Murray Darling Basin (MDB) exacerbated the effect as too did the effect of using wetlands along the river for disposal of sulfate-containing irrigation tailwater drainage. Understanding and better managing this problem is not straightforward.^[17]

In our section of the first edition (2002) of this encyclopedia, we reported the large-scale and expensive use of geotextile vertical wicks to enable the consolidation of sulfidic clay gels in floodplain sections of the main highway linking Sydney and Brisbane on the east coast of Australia. It is pleasing to report that this technique, including acidity management provisions, is successful. However, there have been some limited problems with vegetation-stabilizing batter embankment where deep cuttings through bedrock hills encountered rock materials with very low sulfide content, which was below the natural geological weathering front of the landscape. Fortunately, the acid management systems for the adjacent floodplain sections of the highway were able to neutralize any acid export from the hill sections.

We have become aware of a major problem in building construction, where crushed sulfidic rock was used as fill. The sulfidic material oxidized and when it reacted with contained or added calcium carbonate, gypsum, and other related swelling minerals were formed.^[18] Major cracking of building walls and heave of concrete foundation slabs occurred, forcing occupants to vacate their homes and await repairs. In Ireland, there are more than 20,000 newly constructed houses affected. The Irish situation was only realized in about 2007 following the “Celtic Tiger” burst of economic activity that drove an unprecedented level of construction, mainly residential. Although there appear to have been more than 20,000 claims for damages from the problem, the final number may be much greater because it can take up to 20 years for the damage to become

evident.^[18] The average estimated repair is about 45,000 euros per house and it appears that only the Irish national government has the capacity to cover these costs. This pyrite oxidation swelling problem has also occurred in other parts of the world and particularly in Canada where, again, more than 10,000 houses were affected.^[19,20] It is disappointing that these problems occurred because there is a considerable history of such problems and published literature (e.g., see the works of Maher and Gray^[21] and Britpave^[22]). The pyrite content of quarry rock involved in the Canadian problems was about 1–2%, in the Irish situation, it was about 3–4% (see Fig. 10 in the study by Maher and Gray^[21]). These concentrations are comparable with those we have found in Holocene-age estuarine sediments that produce ASS. However, in the footnote of Table 1 of Britpave's study^[22] that lists the geological strata with a potential for high sulfate/sulfide, Quaternary deposits are said to be “unlikely to contain high sulfate/sulfide levels because conditions during deposition were not anaerobic.” Obviously, Britpave^[22] was not considering the very young materials (aerial and subaqueous) with which the ASS community are involved. Clearly, there is a great need for wider communication between the various disciplines manipulating geological material.

The European Commission of the European Union has developed and published criteria for the definition and management of “end-of-waste” that probably should have been involved with the management of material in this pyrite-heave problem in Ireland. In Australia, the National Coastal Acid Sulfate Soil Coordinating Group (“NatCASS”; that also considers inland ASS) is investigating the development of criteria for definition of sulfurous material and education, qualification, and certification of individuals to provide for the materials' best management. The United Kingdom's Contaminated Land: Application in Real Environments (see www.claire.co.uk) is being investigated initially as a model.

MANAGEMENT APPROACHES

The best management of ASS involves a range of activities that addresses both the issues of minimizing the creation of new acidity from sulfide mineral oxidation and managing the existing acidity in the landscape. Across the range of land uses on ASS landscapes in North Coast of New South Wales (NSW), the existing acidity in the sulfuric layer of the ASS profiles averages about 50 t of sulfuric acid/hectare.^[14] The potential acidity in the deeper sulfidic material of many meters is many times greater than this. Nevertheless, the annual discharge of acidity is <0.5 t/ha.^[23] The degree to which the existing acidity is natural or caused by imposed drainage or application of nitrogenous fertilizer is uncertain.^[14] However, the drainage systems, which markedly reduce the duration of floodplain inundation, provide the conduit for acidity export. Thus, better drainage

management is essential and the NSW sugar industry has adopted this as a mandatory code of practice for all sugarcane growers. Compliance to this code is externally audited annually and only the few instances of inadvertent omissions have been quickly rectified.

Best management of ASS requires knowledge of their occurrence and distribution; the depth from the surface of the sulfidic/sulfuric layer boundary; the existing acidity store; the hydrological behavior of the ASS profiles, landscape, and drainage system; the existing and probable climatic regimes; and, for estuarine ASS floodplains, the magnitude, tidal characteristics, and water quality of the receiving waters.^[24] Frequently, not all of these factors are considered.

EDUCATION AND ASSESSMENT

Although Australian soil scientists and others were slow to recognize the widespread occurrence of ASS, and their importance to better environmental management, this changed rapidly and widely following the 1987 Tweed River fish kill and Easton's seminal paper.^[5]

Mapping of ASS has proven an important tool for better management in Australia. The existence and characteristics of coastal ASS have been mapped by each State (see, e.g., in NSW at: <http://mapdata.environment.nsw.gov.au>, accessed June 2015), and across Australia, and this information is provided in the Atlas of Australian Acid Sulfate Soils that is accessible online through the Australian Soil Resource Information System (<http://www.aris.csiro.au>, accessed June 2015).

In Australia, the assessment and quantification of ASS risk are provided as a guideline in the ever-evolving Queensland Acid Sulfate Soil Technical Manual (version 3.8, accessed June 2015). However, NatCASS is developing a guideline document that will have acceptance across all Australian jurisdictions (personal communication, NatCASS Chair, Steve Appleyard). Such documents are intended to provide all of the information necessary to enable best management of ASS and that will be freely available online to everyone. Obviously, the rapid growth of online documentation of guidelines and reports should greatly facilitate better ASS management because there are increasing issues and problems being encountered by groups and individuals from a great many disparate disciplines and jurisdictions (e.g., see Tichy^[25] and Johnson and Hallberg^[26]).

Education and training of individuals involved in assessing and managing ASS have become important in Australia and several organizations, such as Southern Cross University, provide these as courses in various locations and times. Information on such courses is advertised in the free online biannual publication “ASSAY” (Issues 1–66, available at: <http://www.dpi.nsw.gov.au/aboutus/resources/periodicals/newsletters/assay/>). Free subscription

from email: simon.walsh@dpi.nsw.gov.au includes “subscribe ASSAY” in subject line. This periodical is intended to provide international coverage of articles and research but that depends upon subscribers communicating with Editor Walsh. It was pleasing to see in ASSAY No. 65 that a large number of participants at the 4th National ASS Conference in Perth, WA, in May 2014, described themselves as “consultants.” Also, many of the delegates had previously attended such conferences and/or had undertaken ASS training courses.

AVOIDANCE

A primary preventative consideration with ASS should be an avoidance strategy. Such strategies include the decision not to drain wetlands containing sulfidic material and to divert or relocate a proposed land use or development to another site. If the use of the site is unavoidable, then a management plan incorporating treatment so as to prevent sulfide mineral oxidation and export of any existing acidity is necessary.

Given that most soil scientists and others working with ASS consider that material containing more than 0.25% sulfide require an ASS management plan, it seems surprising and disappointing that the quarry operations in Canada and Ireland were permitted to provide crushed rock fill for construction with a pyrite content greatly exceeding 1%.^[21] Better education and communication about ASS are therefore needed. In assessing the need for avoidance or otherwise, land use planners will consider the relative land values and alternative costs as well as engineering criteria and political necessity. This is a complex assessment process.

OXIDATION PREVENTION

There are a number of possible options here.^[25,26] Separation of sulfidic material and its disposal by capping with material that is impermeable to oxygen and rainfall infiltration is used in the mining industry but sulfidic clays for capping material must be avoided. Decisions to not drain sulfidic wetlands are intended not only to avoid the creation of new acidity from sulfide oxidation but also to address the issue of retaining any existing acidity. Management techniques, such as reflooding to raise the landscape water table, are a means of protecting sulfide minerals from oxidation. However, this technique must also consider the hydrological changes that ensue, such as increasing the export of existing acidity during rainfall-induced discharges. While maintenance of high water tables has beneficial effects, in agricultural land uses with certain crops, this may adversely impact productivity and economic sustainability. As has been seen in the drought problem in the MDB, it is not necessarily easy to always accommodate natural climatic variability. In a rapidly

growing human population, the social impacts must be considered.

ACIDITY CONTAINMENT AND NEUTRALIZATION

Neutralization of ASS acidity by the alkalinity of seawater is the ultimate natural process in the geochemical sulfur cycle. Certainly during the Quaternary sea-level fluctuations, many/most coastal estuary embayments containing sulfidic/sulfuric sediments were excavated to offshore storage during low sea levels and the contained acidity was neutralized. During rising and high sea levels, these embayments were refilled from offshore sediment stores and terrestrial erosion and this material accumulated sulfide minerals from the dissolved sulfate of seawater. The use of this seawater neutralization process with human-induced acidification needs a cautious approach because the downstream ecology of the receiving waters often depends upon the natural-contained alkalinity. The NSW sugar industry, in their required canefield drain management, must apply additional neutralization (usually by agricultural limestone) of any disturbed materials from drains. Since much of the acidity exported in drains from ASS is sourced from very close to the drains,^[14] the elimination of some drains that is possible with laser grading, and egress-pump management to suitable water level above the depth of the ASS sulfidic layer, has been shown to greatly reduce acidity export but also to improve productivity.^[12] In attempting to greatly reduce acidity export from ASS canelands, we have trialed the application of techniques used in the mining industry.^[13,27] The application of other possible options^[25,26] may follow.

CONCLUSION

The understanding of the need and techniques for best management of ASS has markedly changed in the last 20 years, from one predominantly concerned with improvement of their agronomic usefulness to one concerning their environmental impacts. The management of what was previously considered an issue for soil scientists and agronomists must involve environmentalists and particularly the stakeholders. As well, the boundary between the previous “ASS” and “acid rock/mine drainage” has tended to disappear as recognition is made that the chemical and hydrological processes for these two disciplines are associated with the common sulfide mineral oxidation and acidity and dissolved metal drainage processes. The emergence of the “pyrite-heave” problem with using sulfidic fill in the construction industry suggests that there is need for an even wider involvement of researchers, practitioners, regulators, and stakeholders in understanding sulfurous materials. The political and regulatory environment is quite rapidly changing as the problems of ASS are recognized, and it is to be hoped that there is adoption

by all stakeholders and land managers of a culture of environmental stewardship so as to reduce the problems arising from ASS.

Acid Sulfate Soils: Problems

Martin C. Rabenhorst

Department of Natural Resource Sciences, University of Maryland, College Park, Maryland, U.S.A.

Delvin S. Fanning

Department of Environmental Science and Technology, University of Maryland, College Park, Maryland, U.S.A.

Abstract

Acid sulfate soils (acid SS) are, or have the potential to become, extremely acidic due to the oxidation of naturally occurring, reduced sulfur compounds. Because its formation requires sulfate to be present, most acid SS occur in coastal areas. Sulfides within geological deposits remain stable indefinitely in anaerobic environments. Active acid SS form when environmental shifts or alterations expose sulfides to an oxidizing environment. This can be a natural process, such as coastal regression or tectonic coastal uplift, or it may be the result of human activity, such as drainage of coastal areas or earthmoving activities during construction or mining. Whatever the cause, once placed in an aerobic environment, particular bacteria oxidize sulfide minerals and produce sulfuric acid.

INTRODUCTION

What Are Acid Sulfate Soils?

Acid sulfate soils (acid SS) are, or have the potential to become, extremely acidic due to the oxidation of naturally occurring, reduced sulfur compounds. Oxidation forms sulfuric acid causing extreme soil acidity when there is inadequate buffering or neutralizing capability within the soil. In acid SS, pH values < 4 are common, and in extreme instances, pH values below 2 may develop. Soils are sometimes referred to as potential acid SS prior to oxidation of the sulfide minerals, or active acid SS once the extreme acidity has developed (see *Acid Sulfate Soils*, p. 17–19).

In most acid SS, the reduced sulfur compound is the mineral pyrite (FeS_2), but less commonly, elemental sulfur, monosulfide, or polysulfide minerals can cause the same problem. Therefore, acid SS may form wherever sulfide minerals accumulate. The environmental requirements for the formation of sulfide have been specified by numerous workers (see *Acid Sulfate Soils: Formation*, p. 26–30). Because its formation requires sulfate to be present, most acid SS occur in coastal areas although there are cases where acid SS have formed from older rocks or sediments, which at one time were near the coast but are now located in interior settings.

Sulfides within geological deposits remain stable indefinitely in anaerobic environments. Active acid SS form when environmental shifts or alterations expose sulfides to an oxidizing environment. This can be a natural process such as coastal regression or tectonic coastal uplift, or it may be the result of human activity such as drainage of

coastal areas or earthmoving activities during construction or mining. Whatever the cause, once placed in an aerobic environment, particular bacteria oxidize sulfide minerals and produce sulfuric acid. When these soil materials lack minerals to adequately buffer or neutralize the acidity generated, extremely low pH conditions may develop leading to the formation of active acid SS (see *Acid Sulfate Soils: Formation*, p. 26–30).

ENVIRONMENTAL PROBLEMS ASSOCIATED WITH ACID SS

Land Disturbance

Mining

Large-scale earthmoving activity is one important cause of acid SS. Mining activity was one of the first recognized.^[1] Many coal deposits formed in coastal environments contain pyrite either within the coal itself or in the surrounding rocks. Prior to recognition of the acid SS problem, pyrite-bearing soil was commonly left unattended resulting in the formation of active acid SS. Soil surveys in the Appalachian region of the United States include map units for active acid SS such as Sulfudepts. These soils have very low pH in upper horizons, large components of rock fragments, and a high density due to compaction by heavy equipment. For these reasons, extensive areas of abandoned mined lands remained nearly unvegetated for decades. In addition to the problem of acid soils, water (see *Acid Mine Drainage*, p. 6–10) from such acid SS degrades aquatic environments.

Massive additions of lime are usually needed to neutralize soil acidity so that hardy plants may become established. In the last few decades, progress has been made in the United States in recognizing acid SS problems during mining, and both federal (Surface Mining and Control Act of 1977, SMCRA) and state regulations require non-pyritic “topsoil” to be stored separately from the sulfide-bearing materials. During land reclamation, the topsoil is returned to the soil surface providing a better environment for plant establishment and growth.

New mineland reclamation strategies have largely eliminated the problem of barren acid SS on mined land, however, AMD persists. In addition to sulfuric acid, drainage waters carry high levels of iron, aluminum, and manganese, which detrimentally impact the microbial and invertebrate communities of streams.^[2,3] Such waters often become uninhabitable by crustaceans, fish, or other organisms further up the food chain.

Urban development

Geological weathering generally removes sulfides from the upper zone. However, pyrite may be found at depths ranging between 2 and 20 m in some portions of the mid-Atlantic region of the United States. Excavation and leveling associated with building homes, commercial sites, or the construction of highways may sometimes expose sulfide-bearing deposits. Dark gray colors associated with sulfide-bearing materials^[4] and their near-neutral pH when unoxidized sometimes mislead people into viewing this potential acid SS material as good “topsoil.” Unaware of the hazard, sulfide-bearing materials have sometimes been spread unintentionally over the land surface, leading to the formation of active acid SS.

Acid SS formed during urban development pose the same problems as mined lands. Extreme soil acidity presents difficulties in establishing turfgrass and ornamentals. In addition, corrosion of utility structures can be serious when concrete pipes, piers, drainage ways, foundations, streets, and sidewalks are readily attacked by sulfuric acid. The combination of acidity and salinity is particularly corrosive to steel. These acid SS may accumulate ferrous sulfate salts during dry periods and release them into surface waters during rainfall events. There are anecdotal (if not documented) accounts of fish kills in creeks and streams in urbanizing watersheds, where acidity from acid SS has been the likely cause.

Dredging

Opening and maintaining channels for marine traffic represent a nearly continuous operation in many port cities. In the eastern United States, major cities including Richmond, Washington, Baltimore, Philadelphia, and New York were built near the upper limit of navigable waters. When the water bodies are saline or brackish (containing sulfate), materials dredged from the channels often contain sulfide minerals and

represent potential acid SS. Where industry has contributed metals into the estuarine environment, acid SS problems in dredged materials (DM) may be further complicated by the presence of heavy metals in the acid soil environment.

Overboard disposal of DM can lead to release of sorbed and sulfide-bound metals.^[5] Application of DM to land, or creation of new land, may be viewed as good alternatives to overboard disposal of DM, but serious problems remain. Acid SS formed in materials dredged from Baltimore Harbor, e.g., had pH values of 2.5 and contained alarmingly high levels of zinc, nickel, and copper. In the 1980s and 1990s, approximately 600 ha of land were created in the northern part of Chesapeake Bay through the deposition of DM, in an area known as Hart-Miller Island, with similar acid SS problems.

Agriculture

Effects on plant growth

Reclamation of coastal wetlands containing sulfides has been accomplished successfully in the Netherlands and northern Germany, especially where carbonates in the sediments neutralize the sulfuric acid generated through sulfide oxidation. However, there are also cases where the attempted reclamation of coastal wetlands has been disastrous, with soils developing both acidity and salinity problems (such as in Guinea-Bissau in West Africa).^[6,7] Portions of Southeast Asia also have extensive agriculture in areas plagued with acid SS problems, such as in the delta regions of VietNam, Thailand, Malaysia, Indonesia, China, and India,^[8] and similar problems also occur in Australia. The agricultural problems of acid SS are often associated with metal toxicity and nutrient deficiencies.

Acid drainage

Even in areas where agricultural use of coastal acid SS may not pose immediate problems for crops, there may still be environmental difficulties. For example, in areas of sugarcane production in Australia on acid SS, the cane survives by sending roots down into the unoxidized (and non-acidic) portion of the soil. Nevertheless, acidity and metals from these acid SS may be transported through drainage waters into the rivers and estuaries, where dramatic fish kills have been reported.^[9] Strategies to minimize acid drainage from agricultural areas are under development.^[10,11]

REMEDIATION STRATEGIES FOR ACID SS PROBLEMS

Non-disturbance

The old adage “an ounce of prevention is worth a pound of cure” is especially applicable to acid SS, particularly where

the problems are related to land disturbance. It is far better and far easier to avoid the exposure and oxidation of sulfide-bearing soil materials than it is to try to deal with the acidic aftermath. Using geomorphology and modeling techniques, efforts have been made to predict the depths at which sulfides are likely to be encountered within upland landscapes.^[12] This can help prevent the inadvertent exposure of sulfide-bearing materials during construction activity. In cases such as coal and lignite mining, where disturbance may be unavoidable, it has been effective (and is mandated) to separate the sulfide-bearing material from that which is not sulfidic. During landscape reclamation, the non-sulfidic materials are replaced at the soil surface, preventing the development of acid SS in the upper rooting zone for plants.

Heavy Liming

Extremely high rates of liming have, in some cases, been proven effective in neutralizing the sulfuric acid in acid SS. In order to accomplish this, however, liming rates of 25–75 tons/acre may be needed and, in some cases, rates as high as 150 tons/acre have been used. It is important that sufficient lime be added to neutralize both the active acidity and also the potential acidity that remains in yet unoxidized sulfide minerals. A limitation of liming is that it usually can neutralize only acidity within the uppermost portion of the soil (15–30 cm), leaving the subsoil extremely acidic.

Natural Processes of Ripening or Flooding

Rather than trying to quickly neutralize acidity that is being generated through acid sulfate weathering, some have advocated permitting, or even enhancing, the natural oxidation of pyrite in acid SS. This process has been termed *ripening*. Allowing the sulfides to oxidize naturally for a period of time (estimates range from 10 to 50 years) makes the soil more easily neutralized by liming. On the other hand, some have advocated altering soil drainage conditions by flooding or saturation to cause the sulfate to revert to sulfide. While such strategies may be able to prevent or slow the oxidation of sulfides, generally there is insufficient energy (unoxidized organic matter) in the systems to induce significant sulfate reduction in soils that have already become acidic.

Strategies for Acid Drainage

Neutralization

One way to remediate acid drainage has been through direct neutralization of the surface water, either in ponds where precipitation products (usually iron oxides) may accumulate or within the streams themselves. The first efforts involved lining the streambed with limestone gravel. The

high pH of the oxygenated, iron-rich water resulted in the precipitation of iron and aluminum oxide coatings directly on the gravel. This *armoring* of the gravel quickly reduced their effectiveness in neutralizing acidity. Automatic lime dosers have been developed, which periodically add pulverized limestone to a stream based on monitored water pH values. The fine-grained nature of the lime eliminates the problem of armoring, raises the pH of the water, and lowers the levels of soluble metals. The North Branch of the Potomac River, which was once terribly polluted by AMD, has been successfully restored as a recreational trout fishery through the use of lime dosers. Efforts have attempted to use some non-traditional or waste materials to neutralize acidified waters.^[13] Anoxic limestone drains, a variation on neutralization using limestone, were designed to intercept discharging groundwater before it emerged at the land surface. By isolating limestone gravel from oxygenated water below ground using impermeable plastic, it is thought that armoring of the gravel can be prevented.^[14]

Wetlands

Over the last years, constructed wetlands have emerged as a treatment for AMD. Much of the published work emphasized treatment through such processes as neutralization and oxidation, which one might expect to be better accomplished in more aerobic environments than wetlands.^[15] Some have focused more on wetland processes such as sulfate reduction,^[16] and it has been shown that properly designed and engineered wetland systems can effectively remediate the negative effects of AMD through sulfidization and generation of bicarbonate.^[17]

Actinobacteria

Marketa Šágová-Marecková

Jan Kopecký

Crop Research Institute, Prague, Czech Republic

Abstract

Actinobacteria constitute an important part of soil microbial communities and are widely distributed in contrasting environments. Their communities seem mostly structured by pH, but other environmental factors such as soil moisture and organic matter content and quality are also important. A major activity of actinobacteria in soil is decomposing recalcitrant organic matter. Actinobacteria are also prominent producers of secondary metabolites including commercially used antibiotics.

DISPERSAL OF ACTINOBACTERIA

Actinobacteria occupy multiple niches in all environments. They are very important in surface soils and represent up to 63% of the bacterial communities.^[1] Actinobacteria amount to 10^7 colony-forming units (CFU) per gram of soil in grasslands^[2] and to 10^4 CFU per gram of soil in cropped fields.^[3] Actinobacteria occur in soils of all latitudes, freshwater and marine habitats, deep mines, plants, and animals. They exist in less studied soils, e.g., under tropical rainforest, in extremely acidic or alkaline soils, or in sand dunes.

The wide distribution of actinobacteria, however, does not prove the even distribution of particular populations.^[4] It rather seems that the actinobacterial communities are distinct not only over the large areas^[4] but also within one sampling location.^[5]

FACTORS INFLUENCING DISTRIBUTION

Soil bacterial communities are structured both at the microscale and at the macroscale by factors such as soil moisture, soil nutrients, particle size, soil organic matter (SOM) content, and other organisms.^[6] Actinobacteria prefer medium water content although some genera are typically observed in both dry and waterlogged soils.^[7] Some actinobacteria can survive in extreme dry conditions because they predominate in desiccated areas or deserts. Soil moisture content is also related to the spatial variation of nutrients [i.e., nitrogen (N), phosphorus, carbon (C), calcium, and magnesium). Thus, different preferences of actinobacterial species to soil moisture may also be related to their nutrition. In general, cool and nutrient-poor soils narrow the number of actinobacterial genera, with minimum diversity occurring in high mountains (Table 1). Some specific actinobacteria are abundant at high pH,

while others live in acidic soils.^[8] Occurrence of actinobacteria is positively correlated with smaller soil and SOM particles^[9] and negatively correlated with plant root biomass in forest^[10] but enriched in the rhizosphere in grasslands.^[11] Specific actinobacteria are also associated with particular plant species. Actinobacteria are usually saprophytic, so their quantity and diversity often follow that of SOM. Contrasting was their response to fertilizers where an increased proportion of actinobacteria was observed both in an unfertilized site and at a site receiving a high rate of mineral fertilizer.^[12] Actinobacteria are mostly considered K selected, which means that they are adapted to limiting conditions and possess a great ability to compete in stable environments. However, fast-growing actinobacteria with high adaptation ability are also known to live in fluctuating environments.

SEASONALITY OF ACTINOBACTERIA DISTRIBUTION

Seasonal shifts in actinobacteria communities are attributed to changes in SOM composition and water content^[13] and are more pronounced in subsurface than in surface soil, due to higher fluctuations in nutrient availability. In temperate forest, where the biomass of microorganisms is less in summer than in spring and autumn, differences among seasons are even more pronounced for actinobacteria.^[13] The highest proportion of actinobacteria in the microbial community is observed in winter,^[14] and despite a stable count of bacteria throughout the year, actinobacteria are much less frequent in summer.^[15]

ACTINOBACTERIAL GENE POOL

Actinobacteria have a versatile gene pool resulting from frequent rearrangements and gene uptake via horizontal

Table 1 Actinobacterial diversity in relationship to bacterial diversity at selected sites.

Sites	Bacteria			Actinobacteria		
	OTUs	Simpson's 1/D	Simpson's E	OTUs	Simpson's 1/D	Simpson's E
Peat bog (pH 3.2)	37	17.67	0.48	31	8.98	0.29

Notes: Operational taxonomic units (OTUs) represent a number of terminal restriction fragment lengths detected at the particular site for total bacteria and actinobacteria. Simpson's 1/D and Simpson's E are indices of diversity and evenness, respectively, calculated from terminal restriction fragment lengths profiles.

gene transfer events. The actinobacterial genome sizes reflect the complexity of environments they inhabit and need for adaptation.^[16] The extremes are obligate pathogens such as *Tropheryma* sp. (1 Mbp) or *Mycobacterium tuberculosis* (2 Mbp) at the low end and soil actinobacteria such as *Streptomyces* sp. (up to 10 Mbp) at the high end. Closely related species may differ substantially in their gene pools. For example, two members of the genus *Streptomyces* may share only 65% of their genes, while 30% remain strain specific. Even genome size varies among related species depending on their life strategy; e.g., in the genus *Frankia*, which forms N₂-fixing root nodules, the genome sizes range from 5.43 to 9.04 Mbp, with the larger genome size associated with an increased host range.^[17]

VERSATILITY OF ACTIVITIES

Actinobacteria can colonize the plant rhizosphere, where they can parasitize plant roots or benefit from plant exudates, which represent easily available food source. Soil is also a reservoir for many actinobacteria that are important human or animal pathogens and which are represented by strains of the genera *Mycobacterium*, *Nocardia*, *Actinomadura*, or *Rhodococcus*.^[18] Actinobacteria support the growth of plants, e.g., by N fixation or antagonism to fungal pathogens.^[19] They are highly adaptive because they can assist in the development of the climax state of plant communities by supporting the growth of plants and associated bacteria. Actinobacteria represent a reservoir of strains for: 1) biodegradation of pollutants; 2) bio-control inoculants in commercial greenhouse; and 3) symbiotic association with actinorhizal plants that aid

in remediation of degraded soils. In addition, actinobacteria are pharmaceutically important because they are used for production of a majority of antibiotics as well as antibacterial, antiviral, antiparasitic, antitumor, and immunomodulating compounds. Secondary metabolites of actinobacteria are also used in agriculture as herbicides or insecticides.

DOMINATING FUNCTIONS IN SOIL ENVIRONMENT

A primary function of actinobacteria in soil is the decomposition of recalcitrant SOM. Actinobacteria use plant, animal, and fungal detritus as C and energy sources, and they are efficient degraders of organic polymers such as lignin, cellulose, and chitin. Solubilization of lignin is an important activity in C cycling.^[20] Fungi and actinobacteria are key players in decomposition of litter, and their proportion in the microbial community reflects the chemical composition of the litter and the state of the SOM decomposition.^[13] The specific relationship of actinobacteria to SOM quality is reflected by their vertical distribution in the soil profile. Surface soil has a higher number of cultivable actinobacteria than subsoil in grassland,^[2] and the proportion of actinobacteria increases with an increase in depth.^[21] Their numbers follow the site-specific distribution of nutrients in all situations.

SECONDARY METABOLITE PRODUCTION

Actinobacteria are major producers of secondary metabolites, a structurally diverse group of substances, whose functions are debatable.^[22] In the natural environments,

Fig. 1 Percentage of antibiotic-producing actinobacteria strains isolated from differing sites. The antibiotic activity was tested against strains of *Escherichia coli* and *Kocuria rhizophila*. The indicated percentage is a sum of strains exhibiting either of the two tested activities.

secondary metabolites have the potential to modify the structure and functioning of microbial communities by antibiosis or as communication agents. Secondary metabolites of actinobacteria also constitute a large number of clinically used antibiotics. However, the great diversity of genes coding for secondary metabolite biosynthetic pathways is not fully recognized until the first actinobacteria genome sequencing projects. The actinobacteria strains, previously known as producers of a limited number of secondary metabolites, have genetic potential to synthesize a vast number of secondary metabolites. The genetic pool of secondary metabolism is, thus, much more abundant and diverse than the previously estimated and represents great potential for discovery of new or modified bioactive compounds of medical, industrial, and agricultural importance. Further, each soil environment is specific with regard to the secondary metabolites formed and also differs in the percentage of actinobacteria that produce secondary metabolites, specifically antibiotics (Fig. 1).

Abstract

Soil aeration is important to soil processes and plant growth. It can be characterized at various levels of complexity in terms of capacity, intensity, or transport rate. Quantification of oxygen (O₂) transport rates and measurement of concentrations of other important gases besides O₂ provide the best overall characterization of soil aeration for modern investigations, but simpler measurements can be valuable as rapid diagnostics for land managers. Modern instrumentation has made sophisticated characterization of soil aeration attainable at reasonable cost.

INTRODUCTION

Soil oxygen (O₂) enables aerobic respiration of plant roots and soil micro- and meso-flora and micro- and meso-fauna. Its availability can be limited by soil wetness, compaction, discontinuous pores, or high respiration in moist soil due to elevated soil temperature or the incorporation of fresh organic substrate. With O₂ depletion, soil redox potential shifts from oxidative to reducing conditions, hampering plant growth because of less efficient metabolic pathways and release into soil of toxic by-products of reduction chemistry or anaerobic respiration. Several texts are excellent sources for fundamental soil aeration concepts.^[1–3]

Measurements of soil aeration fall into the following three categories: “capacity,” volume of gas-filled void space; “intensity,” partial pressure or concentration of O₂ (or other gases) in the voids; and “transport rate,” the rapidity at which O₂ can be supplied to a point in the soil. Difficulty in measurement increases in the following order: capacity < intensity < rate, as do the value and insight of the measurements.

CAPACITY MEASUREMENT

Capacity describes the ability of soil to contain air. Soil capacity parameters include total porosity, void ratio, relative saturation, and air-filled porosity. These parameters are calculated from simple measurements of soil volume, particle density, bulk density, and water content. Capacity has been used to understand plant growth and yield for over a century. A “rule of thumb” associates impaired plant

growth with <10% soil air volume. Soil attributes affecting capacity include texture, structure, water content, clay mineralogy, and sodium adsorption ratio. Sandy soils have less total porosity than clays, but in sands, the pores are large and well connected. Percent void space tends to increase in finer-textured (more clay), less-compact soils. Because clays have many small unconnected pores and retain water more readily than coarser textured soils (sands), plants tend to suffer O₂ limitation more commonly in clays despite their greater porosity. High soil sodium content or smectitic clay mineralogy (swelling clays) can exacerbate this tendency. Well-aggregated clays often avoid poor aeration because structure enhances macroporosity. Interaggregate pores are larger, better connected, and better drained than smaller intra-aggregate pores which usually contain more water.

INTENSITY MEASUREMENT

Intensity (partial pressure or concentration) measurements have been facilitated by instrumentation, allowing rapid measurement of O₂ and other gas concentrations. The ambient atmosphere is 78% nitrogen (N) and 21% O₂. The remaining 1% contains other gases. Ambient carbon dioxide (CO₂) is about 0.037% and increasing at the rate of 1.5 ppmv/yr. In soil air, the O₂ concentration is <21%. The drop in O₂ below 21% generally corresponds to the CO₂ concentration increase due to the respiration of roots and soil organisms. In soil air, CO₂ is commonly 0.3–1% but can be much higher. In warm wet soil with freshly incorporated organic matter, or where carbonates are abundant, CO₂ can rise above 10%, and where drainage is

restricted, it can reach 20%. When waterlogging occurs and reducing conditions prevail, a few percent by volume of gaseous products of reducing chemistry or non-oxidative metabolism, e.g., methane (CH_4) or nitrous oxide (N_2O), can be present.

Soil air O_2 concentration can be measured using various analytical techniques, mostly depending on whether air is withdrawn from the soil or analyzed *in situ*.^[2,4,5] Withdrawn soil air samples have an interpretation problem stemming from the overrepresentation of macropore composition and/or mixing during convective extraction from the heterogeneous pore sites within the soil matrix. Buried diffusion cavities (artificial porous voids) are sometimes used for sampling points, but questions remain as to representativeness of cavity-equilibrated air. Once withdrawn, soil air samples can be analyzed by wet chemistry, paramagnetic or polarographic methods, or using gas chromatography.^[6,7] Paramagnetic and polarographic instruments can be used *in situ*, but they have limitations. Paramagnetic analyzers require gas flows of tens of cubic centimeters over the sensors. Polarographic soil O_2 sensors are usually covered by membrane. Double membrane probes are used *in situ*, to overcome calibration shifts caused by condensation on sensors. Sensors can be small enough to measure O_2 between small aggregates or within large aggregates.^[8] Samples withdrawn from soil allow for analysis of gases besides O_2 . Knowing the soil O_2 concentration does not indicate if the O_2 consumption rate can be satisfied by the rate of O_2 convection and diffusion through soil.

Soil O_2 concentration <10% by volume indicates poor aeration. However, O_2 concentration per se is an imperfect predictor of plant response. The composition of other soil gases, such as CO_2 , ethylene, and CH_4 , can affect response to a given O_2 concentration. Furthermore, O_2 concentration gives little information about the amount (mass) of O_2 (volume $\times$ concentration) in soil, or the rate at which it can move through tortuous soil pores or across water films and root membranes to reach metabolic sites where it is reduced.^[9] Specific composition of soil atmospheres vary with organic matter and mineral content, soil redox potential, and pH, making it hard for generalizations about soil air trace gas composition as soils become wetter and O_2 concentration decreases.^[1,2]

TRANSPORT RATE MEASUREMENT

Measurements of the rate of gaseous transport in soil are of the following two types: diffusion and convection. To characterize diffusion, Lemon and Erickson^[10] proposed a method to place a small platinum (Pt) wire microelectrode in soil to electrically reduce O_2 . The Pt electrode simulates a respiring root to which O_2 diffuses through air- and water-filled pores and then through a water film surrounding the root. The microelectrode measures the effect of restrictions along this pathway on the O_2 supply to the electrode

surface. The current measured through an electrode tip of known geometry, supplied at steady potential, is related to the steady-state reduction of O_2 supplied by diffusion to root surfaces of similar geometry. The technique became known as the soil ODR measurement (from “oxygen diffusion rate”). Lemon and Erickson’s seminal concept was perfected and field-adapted by others,^[11–13] providing a standardized approach to the technology and a unified interpretive framework. Eventually, commercialization provided the mass production of uniform reliable Pt electrodes and compact portable semiautomated multi-probe instrumentation.

ODR is probably the most common characterization of *in situ* soil O_2 status conducted, and it is well correlated with plant physiological, nutritional, and growth responses. ODR is the only soil O_2 status measurement suited to prolonged remote and nearly continuous measurement of dynamic soil O_2 status.^[14] Factors affecting ODR include water content, electrode contact with soil, presence of reducible compounds, salinity, temperature, and O_2 concentration.^[5,6] Numerous studies^[1,2] have identified an ODR value of $20 \mu\text{g}/\text{m}^2/\text{s}$ as a threshold for a variety of plant physiological, nutritional, and growth responses to limited soil O_2 .

Subsequent ODR advances have been achieved. Electrode miniaturization allows O_2 flux measurements within roots and root microstructures and within intact aggregates.^[15,16] Also, due to potential poisoning of the Pt microelectrodes during long-term exposure to soil by oxides, alternatives to Pt have been developed. Wax-impregnated graphite electrodes (WIGEs) have greater current efficiencies and a wider current plateau than Pt electrodes.^[17] In moist soil, the current plateau region was a function of soil water content, and the response was linear in atmospheres containing as much as 60% O_2 . The WIGEs are less susceptible to oxide poisoning, can be fabricated easily, and are less expensive.

Measurements of soil aeration based on the convection of gas use simple flow permeameters to accurately measure mass flow directly through soil,^[18] or to measure the total air pressure or the difference in air pressure between the atmosphere and soil.^[19] The convection of soil air arises from spatial differences in total air pressures due to abrupt changes in air pressure of the atmosphere, the effects of temperature differences on gas properties, the infiltration and redistribution of water in the soil profile, and the microbial production of gases such as CO_2 , nitric oxide, N_2O , and CH_4 .^[3] Flüher and Laser^[8] developed a hydrophobic membrane probe (HMP) to measure total pressure and partial pressure in soil atmospheres. The HMP consisted of a membrane-covered chamber having a small volume and two teflon capillaries connected to a differential pressure transducer or to an O_2 electrode. A water-repellent non-rigid teflon membrane excluded wet soil from the continuous gas phase of the HMP. The total air pressure in the HMP is compared with the soil surface air pressure to

determine pressure difference between the two locations. Renault et al.^[20] developed an absolute pressure probe to measure *in situ* air pressure fluctuations at the soil surface and at varying depths within the profile. Their probe had negligible signal drift and an accuracy of 10 Pa. The sensitive component of the probe is a differential pressure sensor that functions from -14,000 to 14,000 Pa and senses a pressure differential of 2500 Pa. The signal results from resistance changes in an arsenic-doped silicon membrane that functions as a Wheatstone bridge. The sensor requires 1.5 mA d.c. and its output is -40 to 40 mV. Circuitry converts the input voltage (24 V) into the stabilized current output (4–20 mA), providing a linear relationship between the differential air pressure and the output signal at a given temperature. The characteristics of the air pressure probe allow for *in situ* calibrations.

CONCLUSION

Soil aeration is important to soil processes and plant growth. It can be characterized at various levels of complexity in terms of capacity, intensity, or transport rate. The quantification of O₂ transport rates and measurement of concentrations of other important gases besides O₂ provide the best overall characterization of soil aeration for modern investigations, but simpler measurements can be valuable as rapid diagnostics for land managers. Modern instrumentation has made sophisticated characterization of soil aeration attainable at reasonable cost.

Aeration: Tillage Effects

Dave J. Horne

Massey University, Palmerston North, New Zealand

Robert E. Sojka

Northwest Irrigation and Soils Research Lab, U.S. Department of Agriculture (USDA), Kimberly, Idaho, U.S.A.

Abstract

Adequate soil aeration is important to crop production and environmental protection. Tillage may profoundly influence soil aeration. Although the effect of tillage on soil aeration is dependent on a range of factors and is, therefore, hard to predict, often surface soil aeration is more favorable under well-managed conventional cultivation than no-tillage. Often, these improvements are confined to shallow soil depths and relatively short-time intervals. Where appropriate no-till equipment is used, direct-drilling may have greater potential to improve soil aeration, both in terms of uniformity throughout the soil profile and permanence in time.

INTRODUCTION

Few land management practices have the potential to impact upon soil aeration as directly or rapidly as tillage. Indeed, often, the reason for performing tillage is to modify or improve soil physical properties including aeration. The problems associated with inadequate aeration have been comprehensively reviewed elsewhere.^[1,2] Important effects of limited soil aeration in crop production are as follows: altered nutrient dynamics, a shift from oxidative to reductive chemical/biological reactions, impaired plant growth, and changes in gas equilibria affecting both soil and ambient atmospheres. For example, consider the soil nitrogen cycle that aeration effects via its influence on denitrification and gaseous nitrogen losses, decreased nitrogen mineralization rate, and a reduction in nodulation and symbiotic fixation by leguminous plants.^[3] If the oxygen supply is sufficiently limited, and anerobiosis sets in, then the products of reduction reactions may accumulate to toxic levels. In addition, a depleted oxygen supply may constrain root form and function, such as water and nutrient uptake, and therefore plant shoot performance even when many other soil physical factors are favorable.^[4] Unfortunately, relatively short periods of oxygen shortage can seriously compromise crop performance if they coincide with critical stages of crop growth.^[1] Finally, there are the effects of gas sources and sinks in the soil and transformations of soil gaseous components, and the exchange between soil and aboveground air, on the atmosphere, e.g., diminished soil aeration may enhance the emission of greenhouse gases.^[5]

While the tillage-related literature is voluminous, little of it directly addresses soil aeration. Of necessity, this

short entry critiques only research that has measured aeration status directly—particularly indices of concentration and rate—and will make little or no attempt to draw inferences about the effect of tillage on soil aeration from studies reporting other related soil characteristics. Although bulk density, moisture content, and pore size distribution are related to soil aeration, and so may be indicative of aeration status, their direct relevance to a nuanced understanding of soil aeration is problematical. For instance, measurements of pore space convey little about pore continuity, tortuosity, or stability,^[6] whereas these effects are largely integrated de facto in measurements of oxygen diffusion rate (ODR).

EFFECTS OF SURFACE TILLAGE

Conventional tillage of virgin soil or soils growing permanent or long-term pasture for livestock grazing often improves soil aeration.^[7] In this situation, it is relatively straightforward to prepare a seedbed of good tilth and alleviate any compaction associated with animal or vehicular traffic. However, the timing of such plowing is important, as cultivation of wet soil leads to a dramatic reduction in soil aeration.^[8] If conventional tillage is poorly managed or executed in difficult circumstances (e.g., fine textured soils in humid climates) then relative to the permanent pasture datum, soil aeration may decline within a three- or four-year period.^[9] In the world's major cropping areas, tillage of pastureland is an infrequent occurrence; so a more interesting, if difficult, question is: what are the comparative effects of different tillage practices on soil aeration?

Accurately quantifying the effects of surface tillage on aeration has usually proved difficult. There are issues of both methodology and interpretation to contend with. For example, it has been argued that values for oxygen concentration in the seedbed say little about the quality of the soil air, or its rate of renewal where the roots or organisms are located, and that these factors are likely to be of greater importance than the average level for the whole soil.^[10] Also, some plants can compensate for low soil aeration by the supply of oxygen from one part of the root systems to another via internal diffusion. Another example relates to scale; what effect does a tillage practice have on intra-aggregate aeration in contrast to changes in aeration in the pore space between structural units where roots easily penetrate?

Interestingly, use of the ODR meter, arguably the best technique for field measurement of aeration status, is often unable to routinely and consistently discriminate between tillage treatments. This measure seems better able to reflect wet soil conditions associated with high rainfall and impeded drainage.^[11,12] Yet a significant relationship between ODR and soybean yield has been observed, suggesting that it is only through critical stages of growth that low ODR will negatively impact on crop yield.^[12] Perhaps there are some implications here for the *in situ* monitoring of the effects of tillage on aeration.

The difficulties mentioned above, and the sometimes conflicting research results that have been reported, mean that caution is required when attempting to draw broad conclusions about the effect of surface tillage on soil aeration. The impacts vary dramatically depending on: spatial heterogeneity, the depth in the soil profile under consideration (i.e., above or beneath the depth corresponding to plowing), soil type, the type or configuration of implements, climate, the cropping history of the field, the crop, the crop rotation, and the competency of the operator, especially regarding the timeliness of field work. The quantity and quality of crop residue may influence soil aeration; this aspect has received relatively little attention. Furthermore, interactions between aeration and other soil and crop properties make predictions about the exact effect of tillage on aeration risky. For example, aeration status may interact with earthworm populations and residue levels to effect seedling emergence.^[13]

The above discussion notwithstanding, most published literature has shown that surface soil is better aerated under conventional than other forms of tillage or that plowing enhances surface soil aeration to a greater extent than no tillage.^[14–16] The soil disturbance or loosening associated with tillage implements that invert or mix soil increases air movement in surface soil. In structurally degraded and/or fine textured soil, this increase in aeration may be confined to the inter-aggregate pore space. In an Indian study, tillage gave greater ODR than untilled (control) areas, and the greatest ODR was under moldboard

plow and it was lowest with zero tillage.^[7] Likewise, in a compacted soil in New Zealand, rotary tillage of the soil surface improved ODR rates at 5-, 10-, and 15-cm depths compared with no-tillage.^[11] Enhanced rates of soil carbon oxidation are further evidence of improved aeration under cultivation.

The advantage that conventional tillage affords surface soil aeration may be somewhat transitory in nature both within seasons and across years. Enhanced soil aeration in a conventionally tilled seedbed may be short-lived as a result of soil reconsolidation,^[7] and may disappear by the time the crop becomes well established. The advantage of conventional tillage is likely to be more prominent early in the cropping cycle of a field: after many years of continuous cropping, no-tillage may be more beneficial to aeration status.^[17]

Although conventional tillage may generate more short-term macropores in the surface soil than no-tillage, they may not be as continuous down the profile and may be more tortuous.^[18–20] Therefore, no-tillage may improve aeration more uniformly throughout the soil profile particularly in the horizon just below the depth that corresponds to “plow level.” Where sufficiently detailed measurements have been made, it would appear that not only may air permeability be more continuous or uniform down the profile under no-till, but it may also be more constant across “in rows” and between row positions.^[19]

Implement type will also have an important influence on the effect of tillage on soil aeration. In a summary of a number of New Zealand studies, the effects of some different drill openers on soil aeration are discussed.^[13] They demonstrate the benefits of some drill configurations (e.g., inverted T) relative to others (e.g., triple disk) and illustrate the importance of soil aeration to seedling establishment. In part, differences in tillage equipment, particularly direct-drilling machinery, may account for much of the disparity in the literature on the effects of tillage on aeration. For example, permeability measurements made under no-till treatments established using a triple disc are nearly always markedly inferior to those made under plowing.^[21]

EFFECTS OF SUBSURFACE TILLAGE

Subsurface tillage is practiced to improve aeration deeper in the profile where soils are naturally compact and/or have poor internal drainage. Where deep tillage is employed to improve drainage, it is important that there is an outlet for excess water or deep tillage may exacerbate aeration problems. In a study comparing deep tillage implements, the paraplow (angled shanks operating at 0.5-m depth) achieved more consistent improvement in air permeability at sowing, particularly in the important depth of 15–25 cm, than did subsoilers with straight shanks tilling at either shallow (0.25 m) or deeper (0.5 m).^[11] In addition, all

subsurface tillage treatments increased ODR values to a depth of 40 cm compared with the control. Due to reconsolidation in this humid climate, these advantages had disappeared by harvest.

The hypothesis that, as an alternative to conventional tillage, subsoiling in combination with no-tillage seeding would improve soil aeration, other physical properties, and crop yield in a soil that has become severely compacted following many years of cultivation has been tested.^[11] Some aspects of this study and a subsequent investigation^[22] suggest that, for these New Zealand soils and conditions, despite the significant loosening achieved at depth by subsoiling implements, it was direct seeding that was the important component in the proposed system, and subsoiling contributed or added relatively little to the enhancement of crop yield. In part, this is due to the short-lived nature of the structural improvements generated by subsoiling.^[23]

TILLAGE, AERATION, AND GREENHOUSE GASES

In soil aeration research, there has been a shift in focus away from the study of the movement and use of oxygen and its effects on crop nutrition and growth to the role of soil aeration in environmental protection, e.g., greenhouse gas production and the susceptibility of nutrients to leaching. Indeed, concern about, and investigations of, the relationships between tillage and fluxes, composition and transformations of air into and out of soil are prominent on the environmental agenda. Of particular interest is the effect of tillage practices on the release of the major greenhouse gases: carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O).^[5,24] In addition, there is the suggestion that conservation tillage practices may enhance carbon sequestration.^[25]

Relative to no-tillage, conventional cultivation may result in greater CO₂ fluxes from the soil.^[26] No-tillage may increase the frequency of N₂O emissions and the net fixation of carbon by decreasing CO₂ emissions.^[5,27] Periods of low or zero CO₂ fluxes and very high N₂O fluxes under no-tillage may be associated with periodic reduced gas diffusivity and air-filled porosity, both of which are often caused by heavy rainfall. In general, peak N₂O emissions are mainly associated with heavy rainfall following fertilization particularly with no-tilled soils.^[5] Plowing may decrease the oxidation rate of atmospheric CH₄ in aerobic soils, but this is unlikely to be sufficient to offset the lower N₂O emissions from the soil.^[5]

CONCLUSIONS

Adequate soil aeration is important to crop production and environmental protection. Tillage may profoundly influence soil aeration. Although the effect of tillage on soil

aeration is dependent on a range of factors and is, therefore, hard to predict, often surface soil aeration is more favorable under well-managed conventional cultivation than no-tillage. Often, these improvements are confined to shallow soil depths and relatively short-time intervals. Where appropriate no-till equipment is used, direct-drilling may have greater potential to improve soil aeration, both in terms of uniformity throughout the soil profile and permanence in time. Tillage practices that result in anaerobic soil conditions are likely to promote N₂O production, while those that disturb larger volumes of soil and promote aeration may result in greater emissions of CO₂.

Aggregates: Tensile Strength

Humberto Blanco-Canqui

School of Natural Resources, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

A soil aggregate is a conglomeration of organic and inorganic particles that cohere to each other more than to the neighboring particles. Tensile strength of soil aggregates refers to the stress or force per unit area required to break an aggregate. It is the inherent ability of aggregates to resist the maximum disruptive force without being mechanically fractured along the weakest failure planes. Tensile strength reflects the amount of aggregation in a soil and is a dynamic mechanical property of aggregates changing readily with the wetting and drying cycle of the soil. Intra-aggregate porosity (within aggregate), intra-aggregate bonds, abundance of rupture planes, internal microcracks, aggregate size, clay content and mineralogy, the presence of cementing agents, and overall soil management determine the tensile strength. Aggregate strength depends on the macro- and microstructure of the soils and is a key indicator of soil structural attributes. When an aggregate ruptures in a systematic manner from macroaggregates into microaggregates, it indicates that aggregate hierarchy exists. When an aggregate ruptures directly into silt and clay particles, it indicates that the aggregate hierarchy does not exist. Tensile strength of individual aggregates along with the interaggregate porosity (between aggregates) defines the mechanical nature and behavior of the whole soil.

IMPORTANCE OF AGGREGATE STRENGTH

Tensile strength of soil aggregates is of fundamental importance to soil tillability and plant growth. Aggregate strength affects seedbed preparation, root growth, seedling emergence, activity of soil organisms, and organic matter decomposition.^[1] Soil aggregation and fragmentation depend on the strength of individual soil aggregates.^[2] Aggregate strength also influences the macroscale physical behavior of soils including erosion, infiltration, and permeability. However, the importance of aggregate strength to soil and crop management is often overlooked when dealing with soil-related problems. Furthermore, most soil properties are often determined on the bulk soil rather than on individual aggregates, which are the building units of soil structure.

AGGREGATE STRENGTH AND TILLAGE

Tensile strength of aggregates is a very sensitive indicator of changes in soil structure.^[1] Therefore, any mechanical disturbance of the soil is portrayed in the tensile strength of individual aggregates. Tillage implements exert large loads to fracture and crush aggregates, while vehicular traffic compacts the soil and increases the aggregate strength.

Tensile strength is an important factor affecting the choice of an appropriate tillage method designed to minimize soil disruption. Information about the strength of individual aggregates is useful in understanding the disruptive load exerted by tillage to break soil aggregates. The strength of aggregates is the lowest immediately after tillage and increases gradually following tillage as a result of rainfall-induced consolidation and reduced organic matter content.^[3] Aggregates created by tillage at moisture contents above the plastic limit have higher tensile strength than those created below the plastic limit.^[4] Decline in aggregate strength by tillage can compromise soil quality and long-term sustainability of agriculture. Changes in aggregate strength among different tillage, crop, and soil management practices are not well documented.

IMPACT OF AGGREGATE STRENGTH ON CROP AND ENVIRONMENT

The strength of individual aggregates in interaction with the whole soil affects crop production and environmental quality.^[5] Soil structure is a spatial integrator of all the heterogeneous mechanical properties of aggregates and is made up of individual ever-changing aggregates. Thus, aggregate strength is a useful indicator of the suitability of the soil

structural condition for favorable crop production. Soils with high aggregate strength can reduce seed germination and root growth, thereby reducing crop yield.^[1] High strength may also reduce the uptake of nutrients and water by plants because of reduced porosity and permeability.

Aggregate strength is also indirectly connected to important ecological and environmental processes. Because soil erodibility depends on aggregate strength, the magnitudes of soil erosion and runoff increase in compacted soils with high aggregate strength, whereas soils with low aggregate strength have favorable infiltration and drainage and low runoff. Intensive cultivation in wet soils disperses clay and, following tillage, forms strong aggregates, reducing soil permeability and thus increasing runoff and soil loss.^[5] Data on aggregate strength are useful to identify soils susceptible to compaction and erosion. Management problems related to crop production including soil compaction and plow-pan formation also depend on the integrated effect of aggregate strength. Aggregate strength is thus of paramount importance to the interactions between soil structure and plant growth for favorable seedbed conditions, crop production, and overall environmental quality.

RELATIONSHIP OF AGGREGATE STRENGTH TO SOIL PROPERTIES

There exists a strong relationship between aggregate strength and other soil properties, including moisture (Fig. 1) and texture.^[3] Aggregate strength decreases with increasing moisture content because the bonding strength of organic and mineral particles in aggregates is weakened by the increase in moisture content. Tensile strength of dry aggregates increases with increasing clay content.^[4] Frequently, soils with similar texture and moisture content may differ in their aggregate tensile strength because of differences in organic matter content, clay mineralogy, and soil solution.^[6] Aggregate strength can be sensitive^[7]

Fig. 1 Effect of soil moisture content on aggregate strength.

Source: From Horn & Dexter.^[3]

or insensitive^[1,5] to soil organic carbon (SOC) depending on soil and crop management (Table 1). Increase in SOC concentration may reduce the aggregate strength in the wet state but not in the dry state in which clay content may be the controlling mechanism.

Aggregate strength is also a function of aggregate size (Fig. 2). Strength often decreases with increasing size of aggregates because large aggregates have more planes of failure and weaker matrix points compared with small aggregates. The relationship between aggregate strength and aggregate size can be estimated using Eq. 1, known as the index of friability:

$$\log Y = -k \log V + A \quad (1)$$

where Y is the aggregate strength (kPa), A is the predicted log strength (kPa), V is the volume (mm³) of aggregates, and k is the index of friability.^[2] Wet aggregate strength of soils with high SOC is often higher than that in tilled soils because of greater organic bonding that reduces the slumping of aggregates in water. A simple equation relating aggregate strength to SOC is shown in Eq. 2.

$$\text{Aggregate strength} = a - b \cdot \text{SOC} \quad (2)$$

where a and b are the intercept and slope of the regression model, respectively. The negative slope indicates that aggregate strength decreases with SOC concentration.

Macropores reduce the strength of aggregates. Macropores, planes of failure, and weak spots are abundant in macroaggregates.^[4] The SOC-enriched macroaggregates have lower dry aggregate strength than SOC-depleted macroaggregates. Applied stress concentrates on air-filled macropores and microcracks, propagating these cracks until failure occurs. Aggregates with continuous pores are thus likely to fail more rapidly than those with tortuous pores. Aggregates tend to have higher tensile strength than bulk soil due to their increased bonding of contact points. Interaggregate contacts commonly exhibit weaker planes of failure than intra-aggregates.^[4] Aggregate strength is related to capillary forces, bonding energy between organic and inorganic particles, microbial processes, and soil solution dynamics. Aggregate strength is the result of interactive effects of soil properties and cannot be solely explained by a single soil property in the study by Horn and Dexter.^[3]

MEASUREMENT OF AGGREGATE STRENGTH

Tensile strength of aggregates can be determined using direct or indirect tension (crushing test) tests.^[8,9] The direct tension test quantifies the fracture of soil aggregates perpendicular to the force applied. A challenge in the use of the direct test is the difficulty in preparing samples. In addition, the direct test is more suitable for large aggregates or clods, which are either remolded or grooved into cups.^[2,8] Therefore, indirect tension test is commonly used to measure

Table 1 Relationship of aggregate strength to SOC for different soil types and management

Soil	Management	Strength (kPa)	SOC (g kg ⁻¹)	SOC pool (Mg ha ⁻¹)	References

strength on individual aggregates. Simple apparatus^[10] or sophisticated equipment^[2,8] can be used for the crushing test. The indirect test consists of placing an aggregate between two parallel plates and then applying a known load of force at a constant rate of displacement across the aggregate until it fractures. The tensile strength, Y (kPa), is computed by using Eq. 3:^[7]

$$Y = k \frac{F}{d^2} \quad (3)$$

where F is the breaking force (N) applied to break the aggregate, d is the mean aggregate diameter (m), and k is a coefficient (~ 0.576). Aggregate diameter can be

estimated by 1) passing soil through sieves of known diameter; 2) measuring the longest and smallest diameter with a caliper; 3) calculating the geometric mean of the longest and smallest diameter; 4) adjusting the mean sieving diameter with aggregate mass; and 5) adjusting the mean sieving diameter with aggregate density.^[9] Eq. 3 assumes that the aggregates are homogeneous, are isotropic, and have a uniform deformation and elastic behavior.^[7]

Because tillage is usually performed under high soil moisture, aggregate tensile strength must be measured at moisture contents similar to those in the field at the time of tillage.^[2] Strength is often determined on oven-dried aggregates, which may not reflect the tensile failure of soil during the seedbed preparation. Indeed, drying soil aggregates at 105°C irreversibly alters soil properties. A better approach is to determine strength at known matric potentials by drying aggregates gradually from saturation in Büchner funnels and pressure plate apparatus to simulate field soil moisture dynamics.

CONCLUSION

Tensile strength of aggregates refers to their capacity to resist disruption and is highly sensitive to changes in soil structure. It is a dynamic indicator of soil structural behavior and is important to tillage operations and plant growth. The magnitude of failure of aggregates during tillage can be estimated by determining the tensile strength of individual aggregates. Tensile strength is a valuable indicator for the choice of an appropriate tillage method designed to minimize soil disruption. Aggregate strength affects seedling emergence, root growth, biological activity, SOC

Fig. 2 Relationship of the aggregate strength to the size of aggregates.

Source: From Munkholm & Kay.^[2]

concentration, erosion, infiltration, runoff, and permeability of soils. It affects crop growth and environmental quality. Aggregate strength depends on soil moisture content, SOC concentration, size of aggregates, macroporosity, and clay mineralogy. The most commonly used method to determine the tensile strength of aggregates is the crushing test where failure of an individual aggregate is recorded under a load of force applied. Aggregate strength may not only differ from that of the bulk soil but can also determine the mechanical behavior of the whole soil.

Aggregation

Sjoerd W. Duiker

Pennsylvania State University, University Park, Pennsylvania, U.S.A.

Abstract

Soil aggregation is the organization and binding of soil particles into distinct units that can be separated by the application of energy to soil. When increasing levels of energy are applied, aggregates of most soils break down into smaller aggregates in a stepwise manner. Conceptual models have been formulated to explain this apparent hierarchy of soil aggregation. Different binding agents play roles at specific hierarchical levels. In this entry, the predominant model of aggregate hierarchy and known aggregating agents are discussed.

AGGREGATE HIERARCHY

A common model of aggregation distinguishes the following four levels:^[1–3]

1. Domains, quasicrystals (also called clay tactoids), and assemblages (<2 μm);
2. Clusters (2–20 μm);
3. Microaggregates (20–250 μm); and
4. Macroaggregates (250–2000 μm).

This classification is based on the research in temperate and Mediterranean regions and also seems to apply to moderately weathered tropical soils and volcanic ash soils.^[4] In highly weathered tropical soils with very stable microgranular structure, only one hierarchical level can be distinguished.^[2,5]

MECHANISMS OF AGGREGATE FORMATION

Roots and Vesicular–Arbuscular Mycorrhizal (VAM)

Both plant roots and VAM hyphae associated with roots are important binding agents at the scale of microaggregates and macroaggregates.^[6] Roots physically hold aggregates together, exert a drying effect, and may excrete organic substances that act as glues. The direct effect of roots on aggregation is high with perennial grass species due to the enmeshment of their extensive fine root systems with soil. Annual crops have smaller root systems and therefore a less positive direct effect on aggregation.^[1]

Fungi and Bacteria

Fungi have direct effect on aggregate stability, more than bacteria or actinomycetes. Fungal hyphae act as nets

holding microaggregates together, and fungi and bacteria produce polysaccharides that favor aggregation.^[7] Dead fungi and bacteria act as centers of clusters.^[1] Clay particles adhere to the walls of living fungal hyphae, apparently due to the gluing action of fungal exudates. In sandy soils, roots and fungal hyphae may be the only components responsible for aggregation because sand particles are large and inert and do not interact with charged organic ions.^[8]

Transient and Persistent Organic Matter

Transient organic matter is mostly composed of polysaccharides. Polysaccharides are produced by microorganisms or excreted by roots and bind clay-sized particles together into clusters and microaggregates.^[1] The effect of transient polysaccharides on aggregation is short-lived (generally less than 2 months). Persistent organic matter consists of highly humified organic molecules or polysaccharides protected against the decomposition by aluminosilicate clays or metal oxides.^[9] Persistent organic matter is an important aggregating agent at <2 μm level.

Earthworms

The casts of earthworms become highly stable aggregates that are resistant to slaking and dispersion. The casts contain more silt, clay, organic matter, nitrogen, and exchangeable nutrients and have a higher porosity and stability than the surrounding soil. Besides creating soil aggregates by their casts, earthworms create many pores in the soil as is explained elsewhere in the encyclopedia.

Termites

Termites bring large quantities of clay-sized particles from the subsurface to the surface of tropical soils to build their

mounds. The clay particles are glued together by a sticky fluid excreted by the termites.^[10] The microaggregates thus formed are 0.03–1 mm in diameter and are stable to dispersion by raindrop impact.^[5] Termite activity may be a contributor to the “pseudosand” or “pseudosilt” texture of clayey tropical soils.^[2,5]

Iron and Aluminum Oxides

Iron and aluminum (hydr)oxides are responsible for the very stable structure of many highly weathered tropical soils. However, there is limited evidence to support this conclusion. There is some evidence in which poorly crystalline iron oxides favor aggregation more than crystalline iron oxides.^[11–13] In some cases, aluminum oxides may be more important than iron oxides for aggregation.^[14] The role of these oxides needs more research before far-reaching conclusions can be drawn.

Inorganic Cations

Positively charged cations are attracted to negatively charged aluminosilicate clay surfaces and form bridges between the clay particles or between clay particles and organic matter.^[3] The role of cations in aggregation is primarily at the quasicrystal and domain scale. Differences between cations in their effects on clay flocculation can be attributed to their charge, concentration, size, and hydration.^[15] The ability to flocculate clays decreases in the following order: $\text{Al}^{3+} > \text{Ca}^{2+} > \text{Mg}^{2+} > \text{K}^+ > \text{Na}^+$.^[9]

Aluminosilicate Clays

Clay mineralogy determines to a large extent the basic soil structure of a soil. The most important clay minerals in soils are kaolinite, montmorillonite, and illite. Packs of montmorillonite clays have been termed “quasicrystals” (also called “clay tactoids”), those of illite “domains,” and those of kaolinite as “assemblages.”^[16] Clay particles in quasicrystals are more perfectly aligned than in domains, whereas they are randomly ordered in assemblages. Quasicrystals have a width/thickness ratio >100 , domains <10 , and assemblages <2 . Montmorillonite plates in quasicrystals can come apart when water molecules enter the interlamellar space, explaining the shrink–swell behavior of these clays.

Wetting and Drying and Freezing and Thawing

Wetting and drying cycles are needed to form aggregates. The effect of wetting and drying may be partly due to its effect on microbial activity and the orientation of clay platelets.^[17] Freezing and thawing cycles can break up cloddy soil if water contents are high enough

to separate soil particles. A limited number of freeze–thaw cycles (up to 4) can increase aggregate stability because of localized drying and precipitation of binding agents.^[18]

CONCLUSION

Most soils are built up of a hierarchy of aggregates. Different components determine aggregation at different levels. At the macro- and microaggregate levels, roots and fungal hyphae appear to be the primary factors responsible for aggregation. Clusters are composed of fungal hyphae, and bacterial remains encrusted with clay and silt particles. At the lowest level of aggregation ($<2 \mu\text{m}$), persistent organic matter and inorganic components are responsible for bonds between clay particles. Biological, chemical, and physical processes play a role in aggregation, including the crops grown, earthworms, termites, wetting and drying, and freeze–thaw cycles.

Aggregation: Soil Organic Matter (SOM) and

Cynthia A. Cambardella

National Soil Tilth Laboratory, Ames, Iowa, U.S.A.

Abstract

Soil organic matter (SOM) consists of plant, animal, and microbial residues and organic decomposition products that are associated with the inorganic soil matrix. SOM turnover is coupled to the aggradation/degradation of soil aggregates through the activity of soil microorganisms. In order to understand how soil structure can mediate SOM turnover and formation, it is important to understand how soil primary particles and organic matter interact with each other.

INTRODUCTION

A soil aggregate is formed when closely packed sand, silt, clay, and organic particles adhere more strongly to each other than to the surrounding particles.^[1] The arrangement of these aggregates and the pore space between them is referred to as soil structure. Soil structural stability is the ability of aggregates to remain intact when exposed to different stresses.^[2]

AGGREGATE STRUCTURE

In the late 1950s, it was proposed that clay particles were organized into units called clay domains,^[3] which are defined as groups of clay crystals that behave in water as a single unit. Clay domains are joined to quartz particles through organic matter (OM)-mediated bonds, and these organomineral complexes can be further structured into larger discrete units held together by OM–polyvalent cation bridges. Based on the experiments using ultrasonic vibration to disperse soils, Edwards and Bremner^[4] suggested a model that classified aggregates into the following two groups based on their relative size and stability: macroaggregates (>250 μm) and microaggregates (<250 μm). They observed that the bonds that hold together macroaggregates were easily disrupted, but that microaggregates were quite stable and their structure was disrupted only by applying mechanical energy (sonication) or by chemical treatment. They further postulated that the OM contained within microaggregates is inaccessible to microbial attack and, therefore, stabilized against decomposition.

In 1982,^[5] two Australian scientists, Drs. Judy Tisdall and Malcolm Oades, presented a hierarchical conceptual model of aggregate formation and soil organic matter (SOM) turnover that further refined the ideas published in the late 1960s. The model was based on the observation that aggregates broke down in a stepwise fashion;

macroaggregates >250 μm broke down into microaggregates of 20–250 μm before particles <20 μm were released. These results have been confirmed by a number of researchers^[6–8] and provide the basis for the concept of aggregate hierarchy. The idealized model of Tisdall and Oades^[5] consists of three hierarchical levels of aggregates:

$$2-20\ \mu\text{m} \rightarrow 20-250\ \mu\text{m} \rightarrow >250\ \mu\text{m}$$

Microaggregates of 2–20 μm diameter may be formed by the flocculation of fine silt or clay particles. The flocculation of negatively charged clay particles is increased in the presence of polyvalent cations such as Al^{+3} and Ca^{+2} . OM may enhance aggregation at this level when it forms complexes with the clay and polyvalent cations. It is believed that the OM associated with aggregates <20 μm is primarily of microbial origin, and there is little evidence that any plant debris exists in aggregates of this size.^[9]

The next stage in the hierarchy is 20–250 μm microaggregates. The core of such aggregates may occasionally contain a fragment of plant debris; however, Oades and Waters^[9] reported that the cores of many of these aggregates, especially those between 20 and 90 μm , were void. They suggested that the empty core was due to the complete degradation of the plant debris they originally contained. The stability of this aggregate was maintained by the decomposition products of the organic core.

Macroaggregates (>250 μm in diameter) consist of microaggregates, primary particles, and particulate organic matter (POM) held together by a network of fine roots and vesicular arbuscular mycorrhizae (VAM) hyphae. The surface of the roots and hyphae is covered with extracellular polysaccharides to which microaggregates may become bound. Macroaggregate stability is related to the amount of POM carbon (C) in the soil,^[10] and aggregate formation and stabilization processes in soil are directly related to the decomposition of roots and the dynamics of root-derived POM C in soil.^[11]

The model of Tisdall and Oades^[5] is often interpreted to mean that microaggregates are gathered together by the ramifying effect of roots and stabilized by the enmeshing effect of roots and hyphae. It also suggests that microaggregates are very stable, and the OM associated with them is biologically recalcitrant. A number of researchers have presented an alternative view in which microaggregates are formed within existing macroaggregates.^[12–15] According to this theory, macroaggregates form first through the ramifying effect of plant roots. Fragments of OM, originating as small pieces of plant root, fungal hyphae, or other organic debris may be included in the macroaggregate structure. During the decomposition process, the organic fragment becomes encrusted with clay particles and microbially produced mucilage. The decomposition of the organic core may be retarded. The result is a newly formed, stable microaggregate.

AGGREGATE STABILIZATION AND ORGANIC BINDING AGENTS

Tisdall and Oades^[5] emphasized the importance of organic binding agents to soil structural stability and divided these agents into the following three broad classes based on their temporal persistence in the soil: persistent (humic material associated with polyvalent metal cations), transient (predominantly polysaccharides), and temporary (roots, root hairs, and fungal hyphae).

Humic substances are large, relatively immobile, aromatic molecules produced during the microbial decomposition of plant and animal residues. Persistent organic bonds occur when a water molecule forms a bridge between an anionic functional group (e.g., carboxyl or hydroxide) on the humic molecule and a polyvalent cation (Al^{+3} , Fe^{+3} , and Ca^{+2}) attached to the clay surface. Because of their chemical nature and chelation with polyvalent cations, humic substances are resistant to decomposition but not completely inert.

The origin of soil polysaccharides includes plant and animal tissue; microbial cells; and exudates secreted by roots, hyphae, and bacteria. Plant-originating polysaccharides may be easily decomposed by microorganisms, which in turn secrete polysaccharides themselves. Most polysaccharides are negatively charged, and polyvalent cations serve as a bridge between polysaccharides and clay particles. Unlike humic substances, polysaccharides can be rapidly metabolized by microorganisms; hence, they are considered to be transitory binding agents. If the binding effect of polysaccharides is to persist, they must be continually replenished, or they must be protected from decomposition.

Plant roots, root hairs, mycorrhizae, and fungal hyphae may also serve as temporary binding agents within and between aggregates. Roots form an extensive network throughout the soil, and as they grow, they may enmesh microaggregates and pull them together. In the rhizosphere,

the hyphae of VAM may contribute further to the aggregating effect as they grow into small pores and bind soil particles together.^[16] The hyphae of filamentous fungi associated with decomposing fragments of OM are likely to have a similar effect in the bulk soil.

A summary of the different binding agents and their role in soil aggregation is given in Table 1. It is generally agreed that the humic substances and polysaccharides are the primary organic binding agents for the formation of stable microaggregates. It is important to note that these binding agents are relatively immobile in the soil. The mobile component in the formation of microaggregates appears to be fine clay particles, which may be carried by water through soil pores toward plant roots by matrix or gravity suction. As the fine clays move, it appears that they align themselves parallel to and encrust roots or OM fragments. They may also surround fungal hyphae or encapsulate bacteria. Thus, it is envisioned that microaggregate formation occurs primarily in zones of high microbial activity because this is where the humic substances are being produced. Microaggregates formed in this way would have a core of plant-derived or microbially derived OM.

AGGREGATE STRUCTURE AND OM DECOMPOSITION

In general, it is thought that the humified OM that stabilizes microaggregates is fairly recalcitrant, while the temporary and transient binding agents are more easily mineralized.

Table 1 Summary of the major organic binding agents in the stabilization of aggregates.

Aggregating agents	Aggregation process	Major scale of aggregation
Humic substances	Form strong bonds with soil mineral components	Basis of microaggregate formation
Polysaccharides	Act as gelatinous gluing agents Form organomineral associations	Involved in the stabilization of both micro- and macroaggregates
Plant roots	Enmesh soil aggregates Exude polysaccharides	Agents of macroaggregate formation and short-term binding
Fungal hyphae	Enmesh soil aggregates Exude polysaccharides	Agents of macroaggregate formation and short-term binding
Earthworms	Mix OM and clay colloids together Mix decaying detritus with the bulk soil	Agents of macroaggregate formation

Source: From Haynes & Beare.^[17]

The actual rate at which organic materials are mineralized, however, depends not only on their chemical qualities but also on their availability to microorganisms. The OM bound within soil aggregates may be physically or chemically protected from decomposition.

The physical protection of OM occurs when physical barriers exist between otherwise decomposable substrates and decomposers. The primary evidence that aggregate structure physically protects OM from microbial decomposition is provided by studies in which aggregates are crushed or ground. C and nitrogen mineralization rates increase greatly when the aggregate structure is disrupted. This is attributed to the exposure of OM, which was previously inaccessible to microbial attack.

Chemical stabilization occurs by the chemical interaction of substrate with the mineral part of the soil. As polysaccharides dry, they become denatured and are more chemically resistant to decomposition. In addition, many aggregates are composed of organic cores encrusted by clay particles. During the decomposition process, oxygen is consumed and the cores may eventually become anaerobic. Under these conditions, the solubility of polyvalent cations (Cu^{+2} , Fe^{+3} , Zn^{+2} , and Ca^{+2}) may increase with the result that polysaccharides form complexes with the polyvalent cations more easily. These structures may protect polysaccharides from decomposition.

Differences in the relative stability of macro- and microaggregates are a function of their relative size, as well as the location and lability of the organic binding agents within the aggregates. Because the OM binding microaggregates together is generally assumed to be recalcitrant and in smaller pores that cannot be accessed by microorganisms, it is expected that OM associated with microaggregates will decompose more slowly than that associated with macroaggregates. A number of research studies have supported the assertion that SOM decomposition rates are higher in macroaggregates than in microaggregates for a variety of soils and land use management protocols.^[6,14,18,19]

Abstract

This entry focuses on fragmentation procedures and associated indices for assessing soil aggregation on the basis of the size distribution and stability of fragments after mechanical disruption. When choosing between fragment size distribution and structural stability, procedures will depend on the use to be made of the indices. In general, if the procedure is to characterize the field soil condition without consideration of disruptive processes, then measurement of soil fragment size distribution after low-energy input is recommended. Structural stability measurements are most useful for characterizing soil susceptibility to wind and water erosion. In determining the stability of the soil to mechanical disruption, it is important to measure the distribution of soil fragments relative to an initial undisturbed state.

INTRODUCTION

Soil aggregation can be viewed as the arrangement of primary soil particles into hierarchical structural units, which is identified on the basis of varying failure zone strengths reflecting the characteristics of both the void and the solid phases.^[1]

Direct characterization of soil aggregation can be done by describing morphological features in the field,^[2] using image analysis techniques,^[3] or by measuring the size distribution and connectivity of pores.^[4] Other procedures are based on the partial breakdown of structural units by dispersion or fragmentation and evaluation of the resulting fragment size distribution. In soils, where dispersion–flocculation processes dominate the arrangement of secondary soil units, the use of fragmentation procedures to assess soil aggregation is less precise than the use of dispersion methods.^[5] This entry focuses on fragmentation procedures and associated indices for assessing soil aggregation on the basis of the size distribution and stability of fragments after mechanical disruption.

Aggregates, Fragments, and Particles

Aggregate size and stability are interrelated concepts in the description of soil structure using fragmentation procedures. Assuming separation of aggregates occurs at planes

of weakness surrounding coherent structural units, application of mechanical stress results in soil breakdown into fragments with stabilities greater than the applied stress (Fig. 1). With application of low-energy stress, the resulting fragments will be similar in size to those naturally occurring aggregates. However, with increasing fragmentation energy, the rate of reduction in fragment size will be related to structural stability (bonding energy) between aggregation units (clay packages, microaggregates, etc.). With application of high-energy stress, the resulting fragment size distribution will be independent of further increments in stress and more closely related to the sizes of primary soil particles (e.g., sand, silt, and clay) than the aggregates. Soil fragmentation rarely implies complete disruption of aggregates and can be performed under dry, moist, or saturated conditions.

SAMPLING AND SAMPLE PREPARATION

The processes of breaking down involved in fragmentation methodologies are continuous, commencing at sampling and continuing until the final size distribution of fragments is determined. Thus, the purpose of any aggregation measurement must be well understood before sampling to determine the sampling and handling procedures to be employed. Recommended tools for taking undisturbed samples are shovels or soil core samplers.^[6,7] Samplers

Fig. 1 Idealized changes in soil fragment size distribution as a function of applied mechanical stress. P, median particle size; F, median fragment size; A, median aggregate size; SS, soil structural stability. The subscript indicates the soil type 1 or 2.

with low wall area to volume ratios minimize compression. Air-drying of samples without initial fragmentation promotes the formation of clods, which may not be present in the natural state, particularly when the sampled layer does not dry excessively under field conditions. Low-energy fragmentation of moist samples before air-drying is common. “Gentle” hand manipulation is widely used, but it provides a nonmeasurable energy input that is strongly operator dependent. We favor the application of a standardized low-energy fragmentation procedure such as drop shatter.^[8] Fragmentation and/or compaction can continue during transportation and storage, so adequately sized containers are required. Cohesion of soil increases with drying/storage time.^[9] To be comparable, samples should be treated in the same manner and measurements to be done on samples with the same water potential whenever possible.^[10]

FRAGMENTATION PROCEDURES

Dry Sieving

Dry fragment separation is done with a nested set of rotary sieves or with vibratory or oscillatory movements imposed on a nest of flat sieves. Rotary sieving is accepted as the standard for dry aggregate size distribution measurements for wind erosion assessment.^[11,12] When flat sieves are used, it is important to determine the sieving duration to avoid fragment abrasion. Several studies recommend 30 seconds of vibratory, horizontal, or horizontal-vertical sieving for adequate fragment separation with minimal abrasion.^[13]

Wet Sieving

Wet sieving refers to the separation of soil fragments from an undisturbed sample or a single initial size fraction in the presence of free water or other liquids. Methods that involve sieving a single initial fragment size fraction are preferred because they are less time consuming. However, the selection of appropriately sensitive initial fragment sizes varies among soils. A better estimate of water-stable fragments is obtained by sieving an undisturbed sample over a nest of sieves. The soil water content prior to immersion is a major factor in determining wet aggregate stability. Based on the wetting procedure, different mechanisms of aggregate breakdown can be identified: slaking owing to the fast wetting of dry aggregates, micro-cracking after slow wetting, and mechanical breakdown of prewetted aggregates.^[14] The use of “field moist” samples introduces another variable that may lead to erroneous conclusions.^[15]

Energy Input

Both dry and wet sieving subject soil to forces that are rarely found in the field and which cannot be easily quantified. Several attempts to quantify soil fragmentation energy, on the basis of ultrasonic dispersion or drop shatter, have been described.^[8,16]

SIZE DISTRIBUTION INDICES

The mean weight diameter is a commonly used index for expressing aggregation with a single value.^[17,18] The literature also contains a variety of functions to parameterize the measured mass size distribution of soil fragments (Table 1). Indices based on a single fragment size class have been related to soil processes (e.g., wind erosion^[11]) but are not useful in describing fragment size distributions. When performing the calculations, special care must be taken to avoid inclusion of primary particles (e.g., sand) with sizes similar to that of the measured fragments. Fragment sizes rarely follow a normal distribution, so parameters from the log-normal or Rosin-Rammler distribution models are preferred. A new approach, using fractal theory, has been proposed.^[19]

SOIL STRUCTURAL STABILITY

Soil structural/aggregate stability is a measure of the ability of the soil structural units to resist change (retain structure) in response to application of a mechanical stress (i.e., dry or moist fragmentation, disruption in water, etc.). Although there are a great variety of methods to assess aggregate stability, the ratio or difference in the fragment sizes before and after application of mechanical energy is generally used (Table 2). Defining the low- and high-energy

Table 1 Indices for soil fragment size distribution quantification.

Distribution	Function	Parameters		
		Reference size	Spread of distribution	References
Normal	$P(x < X) = \frac{1}{\sigma\sqrt{2\pi}} \exp \left[-\frac{(x-MD)^2}{2SD^2} \right]$	MD	SD	[20,21]
Log-normal	$P(x < X) = \frac{1}{\log GSD \sqrt{2\pi}} \exp \left[-\frac{(\log(x) - GMD)^2}{2(\log GSD)^2} \right]$	GMD	log GSD	[20]
Rosin–Rammler	$P(x < X) = \exp \left[-\left(\frac{x}{\alpha}\right)^\beta \right]$	α	β	[22]
Gaudin–Schuhmann	$P(x < X) = \left(\frac{x}{x_0}\right)^m$	x_0	m	[23]

Notes: MD, mean diameter; GMD, geometric mean diameter; α , fragment diameter corresponding to the 36.78 percentile of the cumulative probability function; x_0 , diameter of the largest fragment; SD, standard deviation; log GSD, log of the geometric standard deviation; β , Rosin–Rammler exponent; m, Gaudin–Schuhmann exponent. $P(x < X)$ is the fraction of soil structural units smaller than sieve size X.

input levels requires special attention because fragment size depends on both energy input and structural stability (Fig. 1). Aggregate stability indices differ from indices used to describe the fragment size distribution because the former reflects the extent of breakdown relative to an initial condition, while the latter is independent of the soil's initial state.

Structural stability indices are empirical, and comparisons among treatments, soil properties, and/or processes have meaning only when similar procedures are used. The

choice of stability index should be carefully considered in relation to the type(s) of comparison desired.

CONCLUSION

When choosing between fragment size distribution and structural stability, procedures will depend on the use to be made of the indices. In general, if the procedure is to characterize the “field” soil condition without consideration of disruptive processes, then measurement of soil fragment size distribution after low-energy input is recommended. Structural stability measurements are most useful for characterizing soil susceptibility to wind and water erosion. In determining the stability of the soil to mechanical disruption, it is important to measure the distribution of soil fragments relative to an initial undisturbed (low-energy input) state.

Lois Wright Morton

Department of Sociology, College of Agriculture and Life Sciences, Iowa State University, Ames, Iowa, U.S.A.

Abstract

Whenever levees on rivers are breached, there are soil and crop damages in the flooded bottomland areas that impact agricultural management capacities and crop productivity. Earthen levees and floodwalls can be undermined by sand boils, fail after weeks of high floodwater pressure and soil saturation, or even be topped. When a levee fails, there is often a crater lake created adjacent to the levee breach with gullies and land scouring extending into the previously protected lands. As the water spreads out and slows down, sand and sediments are deposited on the bottomlands and in road and drainage ditches. Floodwaters may drown crops and coat the entire flooded land surface with sediments containing a variety of pollutants, nutrients, and contaminants. Restoration of craters, gullies, land-scoured areas, and contaminated sediment depositional sites is necessary if agricultural lands are to be returned to some level of productivity.

INTRODUCTION

Alluvial soils are developed from fine-textured clay and silt sediments deposited in floodplains when rivers overflow their natural banks and flood into adjacent bottomlands. These water-saturated lands experience annual flooding for many months each year as the river levels vary with local and upstream precipitation and snowmelt. Fast moving floodwaters can also transport and deposit sand and gravel onto alluvial bottomlands. When these lands are drained and leveed to protect from river flooding, they are some of the most fertile and productive agricultural soils in the world. Whenever levees on rivers are breached, there are soil and crop damages in the flooded bottomland areas that impact agricultural management capacities and crop productivity. Earthen levees and floodwalls can be undermined by sand boils, fail after weeks of high floodwater pressure and soil saturation, or even be topped. When a levee fails, there is often a crater lake created adjacent to the levee breach with gullies and land scouring extending into the previously protected lands. As the water spreads out and slows down, sand and sediments are deposited on the bottomlands and in road and drainage ditches. Floodwaters may drown crops and coat the entire flooded land surface with sediments containing a variety of pollutants, nutrients, and

contaminants. Restoration of craters, gullies, land-scoured areas, and contaminated sediment depositional sites is necessary if agricultural lands are to be returned to some level of productivity.

River Bottomlands, Agriculture, and Levees

In the United States, the Mississippi River and tributaries drain 41% of the continental land mass including millions of hectares of agricultural lands protected by thousands of kilometers of earthen levees and floodwalls. By 1926, an extensive system of private and public levees along the Mississippi River was engineered to secure agricultural lands and river cities against flooding^[1] from the confluence of the Ohio and Mississippi rivers at Cairo, Illinois, all the way south to the Gulf of Mexico. The U.S. Army Corps of Engineers (USACE) and local levee districts continue to actively manage river levels to maintain navigation and protect against flooding. Prior to the construction of these levees, most river bottomlands experienced crop loss every time the river flooded, but the flooding caused little if any soil damage. Although these massive fortress-like structures seem impermeable, levees do fail for a variety of reasons and allow floodwater to flow through breaches with an intensity that can do substantive damage to agricultural crops. Not only does the crop drown if flooded during

growing season, but considerable soil damage can also occur as a result of the levee breach and lead to the creation of crater lakes, gullies that extend into agricultural lands, land scouring, and sand and sediment deposition on bottomlands as well as drainage and road ditches. Further, as these fast moving waters slow down, the drowned crop and land surface are coated with silt, clay, organic matter, and other chemicals that the water carried. This flooding of crops and soils and the maintenance, repair, and strengthening of degraded levees cost millions of private and public dollars after every levee breach.

Changes in climate,^[2] such as shifts in the long-term seasonality and frequency of extreme weather events, can result in record flooding and droughts and increase the vulnerability and risks associated with managing levee-protected agricultural lands. To understand the impacts of natural and induced levee breaching during high water and flood events, the levee system, the processes and mechanisms by which land scouring and sediment deposition occur, and the remedial activities that are used to repair and guard against levee breaching are discussed in the following sections.

Earthen Levees and Floodwalls

The levee is a massive earthworks designed to contain and channelize the river at flood stage and protect agriculture and other land uses against flooding. It has a flat crown with 3:1 sloped sides. The texture of the materials used in earthen levee construction can vary from silty clay to sandy. Grasses with thick dense roots are planted on the levee to hold the soil in place and reduce the erosive effect of water.

Breaks in the levee, called breaches, can occur when a portion of the levee is eroded or breaks from a subsurface weakness. The higher the levee, the greater the force of the river on the protected land when a breach occurs; thus, a levee as high as a three- or four-story building can explode with the same power and suddenness of a dam bursting. Silty clay levees with a sand core can be affected by vegetation and animal burrowing, which in turn influence the susceptibility of the levee to erode and naturally breach. However, the greatest danger to levee failure is constant water pressure against the levee.^[1,3] The weight of the river can push water underneath the levee and create sand boils that undermine the strength of the levee and its capacity to hold back water. Another type of levee is a floodwall constructed of concrete. These are often built in urban areas at the most erosive points in the river, usually the bend where strong currents and constant pressure of flowing water can erode an earthen levee. Floodwalls may also replace earthen levees when a large quantity of desired soil material is not available or is too costly to transport.

Levee Saturation and Topping

The water-holding capacities of the soil in earthen levees affect its strength to withstand the pressure of the river. During record flooding, the levee can be saturated for a prolonged period and fail, or the floodwater can be higher than the levee and top (run over) the levee crest (Fig. 1). When floodwater starts over the top of the levee, it can cut an erosion channel into and through the levee. Once the floodwater flows over or through a break in the levee, the

Fig. 1 Earthen levee topped by floodwaters resulting in a crater lake.

Source: Reprinted with permission from Olson & Morton.^[5]

river water drops with great force and cuts a crater lake on the inside of the levee. As more water flows through the eroding crack, the floodwaters' speed increases and widens the breach by removing sections of the adjacent levee.^[4] The breach can end up at 100 m or more in width and result in a deep crater lake.

Sand Boils

When floodwaters put significant pressure on floodwalls and levee systems, seepage and sand boils can occur, especially if there are sandy soils underneath the floodwall (Fig. 2) or earthen levee.^[3] Sand boils, including a mega sand boil, occur when the river is at or above flood stage. The bottomland inside the levee acts like an empty sunken basin with the higher floodwater outside the basin creating a hydraulic gradient (Fig. 2). As the water seeks to equalize the pressure on both sides of the levee, a stream of water (called piping) can force its way through even a tiny opening in the riverside of the levee

or floodwall.^[4] Once the water is piped through the soil into the basin, the pressure is released and water shoots up through the porous earth or sand creating a churning or boiling action from which the sand boil is derived.^[6]

Uncontrolled seepage, a major cause of levee failure, creates instability when high water pressure and soil saturation cause the earth materials to lose their strength. Most small sand boils are treated with a 1.5-m-high sandbag ring and filled with water.^[4] The sandbag dike is normally a temporary measure to increase the depth and weight of water over the sand boil in order to decrease the hydraulic gradient across the seepage path and reduce the potential for erosion of earth materials along the piping path.^[6] However, a sand boil can start small and quickly turn into a high-energy sand boil (Fig. 2). In a few hours, it can enlarge dramatically from a few centimeters to 0.6 m in diameter. In the case of a mega sand boil, the crew often has to construct a 15-m ring berm to a height of 2 m or more. When the counterweight of water alone is insufficient to control a mega

Fig. 3 Crater lake extending through 100-m levee breach.

sand boil, it is covered with a few meters of fly ash cinders or other available materials. The treatment of a mega sand boil can require big earth moving equipment such as bulldozers, backhoes, loaders, excavators, and dump trucks and a large crew to contain the mega sand boil and keep watch until the flood stage recedes.

Crater Lakes, Adjacent Gullies, and Thick Sand Deposits

As the floodwater tops or breaks through an earthen levee, it often drops many meters to the bottomland inside the levee and causes deep erosion of the soil and underlying geological parent material (Fig. 1). Most crater lakes (Fig. 3) are several meters deep.^[3] As the floodwater flows rapidly into the previously protected bottomland, gullies originating adjacent to the crater lake are cut into the soil and can extend 10–100 m beyond. Geologic materials, soil, sand bars, and sediment carried down river and from the degraded earthen levee are deposited in the bottomland after the floodwaters slow down (Fig. 1).^[3] The thick sand can be deposited on agricultural crops (Fig. 4) and other

Fig. 4 Sand delta covering corn field with tree residue from between river and levee.

Fig. 5 Gully fields on O'Bryan Ridge with levee in background.

vegetation in the land surface as well as in drainage and road ditches.

Land Scouring and Gully Fields

After a levee breach occurs and the fast current of the water has created crater lakes, extended gullies into the bottomland (Fig. 5), and scoured the land surface, the speed of the advancing floodwater begins to slow and deposit sand particles on the bottomland in large sand deltas. As the floodwaters continue to slow, the silts drop and then the clay and organic particles settle out and coat plant residues and the land surface.^[8,9] Significant land scouring can result in many hundreds of hectares of land losing centimeters of topsoil after each levee breach.

Levee-protected bottomlands normally have very little slope and are almost flat but can contain higher natural levees formed from old oxbows cut off from the river (Fig. 6). An oxbow is the wide curve portion of a meandering river channel. The floodwaters will pond in front of these meander scars or natural levees. When water flows over a natural levee ridge and drops down to another alluvial bottom, it concentrates and creates an eroded channel or waterway. This erosion process is called hydraulic jumping. As high-energy floodwater flows into the newly created waterway, it can cut into the ridge and carve additional new channels and gullies.

These deeply eroded soils or gully fields (Fig. 8) are extremely difficult and costly to reclaim.^[8] Often bulldozers are used to push in the tops of the vertical gully walls to fill in the bottom and then grade the side slopes. The pushing of topsoil into the gullies puts the soil material on slopes that are highly erodible, and the exposed subsoil and parent material of the scrapped areas lower the productivity of the original soils. Topsoil must be hauled in to raise the soil organic carbon content of the soil if the land is to be returned to the previous level of agricultural productivity. Terracing is another option for reshaping the side slopes above the gully

Fig. 6 Land scouring and gully formation when floodwaters flow over a natural levee ridge.

bottom. This approach will still result in the loss of long-term soil productivity and crop yields because the newly created soils will be less productive than the original soils as a result of mixing topsoil with parent material low in soil organic carbon. Reclamation efforts to restore these land-scoured ridges and gully fields can cost hundreds of thousands of dollars and are likely to still result in lowered soil productivity and crop yields when compared to original crop yields. When gully fields are created by levee breaching, the land use may change. Gullies that are not reclaimed will collect water and become wetlands. This loss of agricultural land to ponds and wetlands results in a net loss of agricultural productivity in the region.

Effect of Growing Crops and Residue on Erosion and Deposition

Crops grown in the Mississippi and Ohio River bottomlands are primarily wheat, corn, soybean, and forages. Depending on the time of year, the land cover may include these crops in various stages of growth or only plant residues remaining from the previous year's crop such as soybean stubble, corn stalks, and wheat stubble. When spring floods occur, winter wheat and forages are growing and are likely to drown. However, these fully developed plants can hold the soil in place and prevent the land scouring. Sediment carried by floodwaters is caught by the wheat and forage vegetation and deposited on the crop. If the levee breaching and flooding occur in the spring before corn and soybeans are planted, only previous crop plant residues are protecting the bottomland soils. These plant residues are often picked up and carried along by floodwaters and lose their protective capacity to prevent land scouring. When the flooding

and levee breaching occur later in the growing season, the soybean and corn plants help slow the speed of the floodwaters and anchor the soil. After the floodwaters recede and the land drains, the soil can either be dried and planted or be left idle but tilled to eventually mix in the sediments to help dry out the fields depending on the timing of the flooding. Thin layers of silt and clay deposits can be treated by sunlight, drying, and tillage to incorporate into the plow layer. Tillage equipment, such as chisel plows and moldboard plows, can be used on the areas with thin sand deposits (<15 cm) in an attempt to mix the sand into the underlying bottomland with silty and clayey topsoil.

Crop damages depend on the type of crops commonly grown in the area and the timing of the levee breach and subsequent flooding. If flooding occurs in the growing season of a crop and the plants are under floodwater for 24–36 hours, the submerged crop will drown and can result in a total crop failure for that year. If flooded early in the growing season, the crop can be replanted but usually results in lower yields. Crop insurance can provide replacement for a portion of the income for farmers who have purchased it.^[10,11]

Sediment Deposition in Road and Drainage Ditches

After a levee breach and flood event, road and drainage ditches in the area are filled with sediments and sand, sometimes as much as 1–2 m deep. Excavators are usually brought in by either the county or drainage districts or Natural Resources Conservation Service to remove debris and sediment that block drainageways and ditches to speed up the drainage process and to accelerate the drying out of low lying areas.^[8,9] The sediment in private drainageways

of most qualified landowners can sometimes be partially financed by the U.S. Department of Agriculture Emergency Services Agency's Conservation program. The local drainage district often provides additional matching funds for these projects.

Levee Repair, Sand Delta Removal, and Crater Lake Filling

If the funds are available, the USACE or the farmer levee and drainage districts usually begin reconstructing levees immediately after the floodwaters have drained. Sometimes, the levee is repaired in stages if the funds are insufficient for the entire reconstruction of the levee. Restoration and repair of the levee to the original height or higher is usually a concern of the landowners flooded by the levee breach.^[9] The sand deposits are often collected and used to fill in the crater lake and then topsoil is trucked in and spread over the crater lake to restore the previous land use. The thick deltaic sand deposits can be 3–20 ha in size and between 0.1 and 1 m deep. Both the crater lakes and the thick sand deposits can result in a permanent loss of agricultural productivity^[2,11] if they are not filled in or removed. The transported topsoil may come from other levees on smaller tributaries and drainage ditches or other adjacent soil deposits. The reconstructed soil profile will still be less productive than the original soils.

Damage to Farm Building and Homes

When a levee breach occurs, there is always the risk that lives and property may be lost or seriously harmed.^[1] When a levee breach is eminent, the U.S. National Guard usually sweep the area to make sure the people living and working in levee-protected bottomlands are evacuated. There is also a high risk of damage to the homes, barns, and other structures on these flooded bottomlands.^[12] Buildings can be impacted by the force of the flowing floodwater and become fully or partially submerged in the floodwater. Water pressure can result in the loss of the lower half of entire walls, damage wooden floors, or destroy structures completely. In addition, farm structures (sheds, barns, and grain bins) can be damaged, and depending on insurance coverage, only a few of these structures may be repaired.

Protected and Unprotected Agricultural Lands

River bottomland areas that are not protected by levees usually receive a thin layer of silt, clay, and organic matter during flood events. The crop is lost if flooding occurs in the growing season, but soils do not usually suffer permanent damage.^[13] This is not the case where levees fail. Levees can fail as a result of a sand boil or by levee topping. Blowout holes or craters can be created between 1 and 10 ha in size and can hold water. Fast-flowing water can remove hundreds of meters of

levee embankments and can erode thousands of cubic meters of soils and underlying outwash parent material to depths of many meters below the base of the earthen levee when the levee breaks.^[4] The force of the rushing water can uproot trees growing between the river and the levee and deposit them, as residue, on the previously protected floodplain. Deep gullies can extend a few hundred meters into the bottomland, and hundreds of mature trees can be transported hundreds to thousands of meters. Deltaic sand deposits up to 1 m thick cover many hectares on the floodplain at each breach site with additional hectares covered with a thin layer of sand. The remaining hundreds of hectares of previously protected floodplain soils receive a thin coating of silt and clay and can remain under floodwaters long enough to drown the year's crop if it was planted and not already removed by the wall of advancing floodwater. After a few weeks, the floodwater usually drains from the bottomland and back into the river or slowly evaporates and infiltrates bottomland soils sufficiently for the local landowners to begin the task of moving the trees from near the blowout holes and floodplain and begin filling in the craters and gullies.^[4]

CONCLUSION

Climate change will amplify the risks associated with snowmelt, rainfall, runoff patterns, and river flooding. As the odds for certain types of weather extremes increase in a warming climate, farmers, rural residents, and supporting institutions as well as public and private levee districts will need short- and long-term strategies to sustain their system of levees, address breaching events and reclamation of agricultural lands, and put in place adaptive management plans that anticipate events. Levees are complex engineered systems coupled with natural and social systems. Levee redesigns must account for not only the risks to the engineered system but how to make the social, economic, and environmental systems more resilient. One need is to better understand how the soils are affected by flooding and levee breaching and their capacities to support to agricultural productivity.

The following three recommendations are offered to provide valuable data in assessing soil degradation and to guide restoration in making levee-protected agricultural bottomlands more resilient: 1) improve characterization and measurement of eroded soils and distribution of sediment contaminants after levee breaching; 2) assess contamination effects on soil productivity and long-term agricultural production in order to understand the impacts of flooding on agricultural soils; and 3) evaluate reconstruction investments needed to repair levees based on return of the land to productivity and increased landscape resilience by reducing vulnerability to future flooding and levee breaching stress.

Abstract

Roots represent the belowground component of vascular plants and are one of the most important plant organs responding to changes in growth conditions. The growth of the root system is genetically determined. However, the root formation of crops can strongly be affected and controlled by agricultural management. Roots grow by a simple branching process leading to lateral roots emerging from the main root. Generally, the root biomass may comprise almost half of the plant biomass.

ROOT GROWTH

Roots are cylindrical organs without nodes and internodes. The growing point is located at the root tip, followed by a small section containing numerous fine roots or root hairs. Because of the small size and multitude of these root hairs, the explored soil volume and uptake of water and ions by the plant roots increase drastically.^[1] The roots build a root system in the soil, with a total length far greater than that of the aboveground shoot system. Predominantly, the roots are located within upper soil layers, which have a sufficient water and nutrient supply. However, they are able to penetrate the soil very deeply to reach the groundwater.

Dicotyledonous plants have an allorhizous root system, consisting of a gravitropically growing main root that continuously generates new lateral roots. These secondary roots of first order grow plagiotropically in horizontal direction. Monocotyledonous plants have a homorhizous root system. Seminal roots initially developed during germination from the embryonic nodes die back, and morphologically equivalent adventitious roots developed from lower stem nodes replace them. The life span of roots varies between a few days and the whole life period of the plant.^[2,3]

ROOT FUNCTIONS

The main functions of roots are anchorage of the plant in the soil and absorption of water and nutrients. Furthermore,

roots transform and distribute absorbed ions, store photosynthetic products, and synthesize growth regulators.^[4] Their effectiveness depends on the extent of the root system and varies with age and physiological condition of the plant. Plant roots are capable of entirely changing the soil chemical milieu in the rhizosphere by their metabolic activity.^[5] Generally, the nutrient availability for roots depends on the actual amount of dissolved ions and the capability of the soil to replenish ions from the organic and mineral nutrient pool. Roots are also producing plant growth regulators, thereby influencing shoot growth, photosynthesis, senescence, water balance, and phototropic and geotropic reactions.^[6]

FACTORS INFLUENCING ROOT GROWTH

Agricultural crops were selected for rapid growth according to increasing nutrient and water use efficiency. Crops respond to optimal resource availability with an increase in growth and yield. Arable crops are characterized by a relatively low root-to-shoot ratio. In the course of plant breeding, cultivated crops lose their natural high degree of phenotypic and physiological variability. Therefore, agricultural crops may be severely influenced by external stress factors such as soil compaction, water and nutrient deficiencies, and variations in temperature or diseases.

Roots of annual plants can reach up to 2 m depth. However, a sufficient supply of nutrients and water in the upper soil horizons may result in lower rooting

depths. Before exploring deeper soil horizons, roots absorb water from the upper soil layers.^[7] Mechanical soil compaction below the surface soil (e.g., plough pan) impairs the soil porosity and its water and oxygen content and thus the root penetrability. Consequently, shallower roots develop in soils with physical constraints. Furthermore, the number and the total length of roots decrease, and the regeneration of fine lateral roots and their activity are suppressed; e.g., the root diameter of cereals increased by 25% with an increase in soil depth of compacted soils.^[8] Roots mechanically stressed consume more assimilates and have low nutrient absorption, higher mortality, and a higher root turnover.^[9]

The soil water content is particularly important to root growth. Short-term water deficiency leads to the stagnation of the root growth with direct consequences to shoot growth and yield.^[10] Prolonged low water supply promotes root expansion to deeper soil layers. Extensive root branching patterns, however, enable plants to cope with long-term water stress. Under drought conditions, a favorable potassium (K) supply reduces the effects of water stress; e.g., beans grown under suboptimal soil moisture conditions increased the root dry weight up to 80% and the root length up to 35% with the application of K.^[11]

The stimulating effect of nitrogen (N) on root branching enables plants to use resources with a higher efficiency. This response is especially important to the acquisition of more immobile nutrients such as phosphorus.^[12,13]

In a field experiment, balanced fertilization predominantly affected the rooting intensity of winter wheat

(*Triticum aestivum* L.) within the upper soil horizons. At flowering, the optimal nutrient supply by combined mineral and straw/farmyard fertilization stimulated the development of finer roots with more branches, without significant differences in the total dry weight (Fig. 1). The input of carbon (C)- and N-containing organic material by root and crop residues was approximately higher by 1 t/ha in plots with organic fertilizer compared to mineral fertilization.

The root system development of cereals follows a similar pattern. During the tillering and shooting phase when the plants show the most intensive shoot development, the active root mass increases until flowering. In the topsoil, however, the amount of living roots permanently decreases during the following growing stages. The rooting depths of cereal plants can extend from 60 to 200 cm, influenced by the soil compaction and the water conditions.^[14,15]

Generally, up to 90% of the total root biomass is located within 30-cm depth, whereas the most intensive rooting occurs in the upper 10 cm of the soil. Below the topsoil (the 30-cm horizon), the root density proportionally decreases with the depth. In sandy soils, where nutrient losses by leaching can be high, growing a catch crop contributes to the enhancement of the soil fertility, e.g., by the improvement in the soil structure, maintenance of organic matter content, and the reduction of nitrate leaching. Catch crops differ in rooting depth and root dry matter (DM) production (Fig. 2). The amount of N stored temporarily within roots and shoots may reach up to 160 kg/ha for oil radish (*Raphanus sativus* L.), 120 kg/ha for phacelia

Fig. 1 Root density and root DM of winter wheat (*Triticum aestivum* L.) within the topsoil (0–30 cm) of a loamy sand and C and N inputs by crop residues after harvest.

Fig. 2 Root DM (t/ha) of catch crops in a sandy soil at the end of the growth period.

Source: From Rogasik, Smukalski, et al.^[16]

(*Phacelia juss*), and 100 kg/ha for lupines (*Lupinus luteus*), respectively.^[16]

The annual average input of organic matter from roots and crop residues to agricultural soils of the temperate zone ranges between 0.56 and 6.06 t/ha/yr, respectively, depending on the crop species.^[10] Postharvest residues including plant roots are fundamental to the maintenance of soil organic matter stock.

Soil tillage strongly affects the soil physical properties and thus the development of the root system. In long-term field experiments in Germany, conservation tillage encouraged more intensive rooting within the upper 30 cm soil depth compared to conventional tillage including ploughing (Fig. 3). Ploughing of compacted soils can increase root biomass. However, differences have been observed between the root length density of

cereals (*Secale cereale* L.) and beans (*Vicia faba* L.) by different tillage methods. Cereals have a widely branching root system, consisting of adventitious and many fibrous roots, whereas the root system of beans is comprised of tap root systems with laterals.

CONCLUSION

Roots are continuously produced and turned over during the entire vegetation period. For their growth, appropriate nutrient supply, soil organic matter content, and the physical soil conditions within the rooting zone play an important role. The balanced application of suitable amounts of mineral and organic fertilizers can stimulate the root development. Roots are an important input of easily decomposable organic matter into arable soils. Roots also contain very stable organic compounds like lignin. During the decomposition processes, the nutrients organically bound within the root biomass are released over a longer period and are available again for plant nutrition. Crop residues and roots remaining on the field after harvest act as a temporary C and N pool.

Abstract

In the 1990s, prospects arose for income from carbon sequestration with the end of the decade seeing formulation of the Kyoto Protocol. Discussions of the potential for soil carbon trading were widespread. However, in the ensuing 15+ years, the actual incidence of trading soil carbon for money has been quite low. Here we explore the background and motivations for soil carbon trading, mechanisms for trading, realized experience in markets, reasons for low levels of trading, and possible actions that might enhance chances.

INTRODUCTION

In the 1990s, prospects arose for income from carbon sequestration with the end of the decade seeing formulation of the Kyoto Protocol. Discussions of the potential for soil carbon trading were widespread. However, in the ensuing 15+ years, the actual incidence of trading soil carbon for money has been quite low. Here we explore the background and motivations for soil carbon trading, mechanisms for trading, realized experience in markets, reasons for low levels of trading, and possible actions that might enhance chances.

BACKGROUND: WHY TRADE SOIL CARBON

The reasons for considering trading soil carbon come in large part from an understanding of the carbon cycle and the link between climate change and atmospheric concentrations of greenhouse gases (GHGs). The motivation for

and logic behind GHG control has been well discussed in the series of Intergovernmental Panel on Climate Change (IPCC) documents^[1–3] along with many other publications including the U.S. National Academy of Sciences.^[4] These arguments will not be reproduced here as there is already a voluminous literature.

In terms of soil carbon sequestration, many arguments have been made. Thus, rather than repeat them, we refer the reader to the many pieces by Lal and associates, the conference proceedings by Rosenberg, Izaurralde, and Malone,^[5] and the IPCC working group III chapters on agricultural mitigation^[6] along with likely other chapters in this book.

Additionally beyond GHG motivations, there are other reasons why one might wish to engage in soil carbon trading. Just to list a few of these:

- Many of the mechanisms for increasing soil carbon are well-known practices that have also been advocated for soil conservation, erosion control, runoff reduction, and water quality improvement (Lal et al.^[7] and Follett and

Kimble^[8] discuss these items as likely do other chapters in this book).

- Increasing soil carbon content is often associated with increasing soil organic matter with accompanying benefits for crop yields, nutrient holding, and water retention plus a number of other benefits that are well known to those who would read this book (for more again, see Lal et al.,^[7] Follett and Kimble,^[8] or other chapters in this book).
- Market trading of soil carbon for money would enhance farm income and provide an alternative form of income support to farmers. Furthermore, the agricultural role in the market for offsets is likely to be small and thus the demand for soil carbon offsets is likely to be much more elastic than typical agricultural commodity demands. This means that most of the benefits of those markets will go to producers rather than mainly accruing to consumers as is commonly found in analyses of new agricultural supply enhancements.
- Many have discussed cobenefits in terms of soil and water quality, biodiversity, and other items (see Lal et al.,^[7] Follett and Kimble,^[8] Elbakidze and McCarl,^[9] or other chapters in this book).
- Agricultural soil carbon offsets have been argued to be a potentially cheap source of GHG offsets^[10,11] and thus may allow society to achieve atmospheric GHG reductions at a lower price, greatly lower in the cost of climate change action.^[12,13]

THE CONCEPT OF TRADING

Trading soil carbon is a means of achieving reductions in environmental damage by harnessing the power of the marketplace as suggested by Baumol and Oates.^[14] In particular, suppose policymakers develop a program to limit society's net emissions of GHGs and require all emitters to cut back by some given percentage. Under such circumstances, some emitters may find it very expensive to cut back emissions, whereas other parties may find it substantially cheaper or may have cheap ways of employing sequestration activities. If a marketplace is established, which allows high-cost emitters to meet their emission reduction obligations by, among other actions, buying emission reductions or sequestration increases that are carried out by other parties, then the overall societal cost of reducing net emissions would be reduced. Such an approach was advocated in the Kyoto Protocol.^[15]

In the soil carbon setting, the basic trading concept is to allow soil sequestration to be sold into the marketplace to provide emitting entities with an alternative way of meeting their emissions reduction obligations by paying farmers a smaller amount to increase soil sequestration. This would introduce another commodity that agriculture could sell.

WHY HAS TRADING BEEN LOW

Now let us turn attention to the questions of why there has not been much trading. This really boils down to three reasons:

- Trading volumes and prices have been low.
- Agriculture has not really been let in the door.
- Soil carbon brings with it some unique challenges.

Each of these is discussed individually.

Trading Volumes and Prices Have Been Low

It is almost uniformly a fact that in general GHG markets once up and running, the price has been smaller than expected. Toward the end of its run, the Chicago Climate Exchange (CCX) prices were in the pennies, the European price in the 2015 market fell to three euros, and the Environmental Defense Fund indicates that prices from the first year of California trading are lower than expected.^[16] There is also the possibility of trading underneath the Clean Development Mechanism and in trading systems in New Zealand, Australia, and Alberta. However, in those cases soil carbon trades have either been non-existent or exhibit certain problems as are discussed below.

The largest exchange and one often pointed to is the European emission trading system (ETS); however, this certainly has had some troubles. Burtraw^[17] argues that the ETS is “hobbled” mainly because it exhibits low prices. Burtraw^[17] attributes the low prices to overestimates of the costs of compliance, the economic downturn, the influence of carbon taxes and other complementary policies in European states, an influx of international credits, the banking of excess emission reductions from prior years, and early auctioning of next year's allowances. The incidence of low prices certainly limits the demand for potential offsets like those from soil.

However, when considering why U.S. credits have not been trading there are other causes. Certainly in the United States, we have seen a decision to not ratify the Kyoto Protocol, a lack of passage of any cap-and-trade-related bills in Congress, a failure of the voluntary CCX, the incidence of low prices under the Northeast Regional Greenhouse Gas Initiative scheme forcing an early 2014 redesign and a slow evolution of the California market.

Generally then trading volumes have been low because of low prices and/or a lack of some sort of regulation, which provides an incentive for emissions reductions. As a consequence, there has not been much expressed market demand for bringing agricultural soil into the picture. However, there is some hope of increased U.S. trading as stimulated by the EPA proposal regarding GHG emissions from power plants.

Agriculture Has Not Really Been Let in the Door

While the trading volumes have been low in general, they have been yet lower in agriculture. This basically is because agriculture has been virtually universally treated as an offsets sector, not a capped sector, and one that is either precluded from some of the larger schemes or included but only in very selective ways. Furthermore, where included, the trading rules have not necessarily guaranteed GHG net emission reduction success. Reasons grouped into physical factors, market demand factors, and attitudes are discussed in this section and the rule question in the next section.

In terms of agriculture being treated as an offset sector, many agricultural interests have generally argued that agriculture should not be subject to a cap on emissions. This offsets role has been adopted in virtually every trading environment and means that agriculture is not to be forced to reduce its emissions but rather to operate as a source of offsets. This would involve, for example, reducing manure-based emissions or increasing sequestration and in turn being able to create saleable offset credits that can enter into the marketplace and purchased by, for example, large industrial or electrical power generating concerns for use in meeting their obligations. However, the ability to do this has been limited by eligibility criteria as discussed in the next paragraph.

In terms of agriculture being precluded from some of the larger schemes, the largest volume market is the ETS and there are no provisions for any agricultural participation in that scheme. IPCC^[3] also indicates that agricultural participation in the New Zealand scheme has been delayed indefinitely and that most of the other schemes only allow agricultural participation on a restrictive basis (as reviewed in IPCC^[3] in Chapters 11 and 15). This largely involves afforestation/reforestation (generally ignoring soil carbon) and manure methane along with some agricultural residues for biomass energy. The main reasons for this are the likely ease of monitoring of the standing tree, crop inputs to bioenergy, and manure emission recovery coupled with the point nature of emissions from the allowed practices. California has a draft rice protocol that also has some soil carbon-related features but is mainly focused on methane. Alberta has features regarding control of nitrous oxide (N₂O) emissions and fuel use associated with the management of fertilizer, manure, and crop residues. Australia also has features under the carbon farming initiative, although the first possibility for payment for land moving from crops to pasture is just emerging.

Soil Carbon Brings With it Some Unique Challenges

While trading and agricultural participation therein has been limited, there are also some characteristics of soil sequestration, which complicate and have been seen to limit trading. These characteristics involve physical factors,

demand factors, and attitudes toward soil sequestration. Each is discussed below.

Physical factors

The main physical features, we discuss here are spatial distribution of carbon, timing of sequestration accumulation, heterogeneity of sequestration, and uncertainty in accumulation.

Soil carbon is spatially ubiquitous with it dispersed throughout the landscape. Furthermore, unlike sequestered carbon in standing trees or carbon injected then sequestered in a deep underground aquifer, it is not directly observable by eye or simple flow instruments. Rather one can sample and measure it at sample points and then infer based on the samples stored in a particular area. However, it is not practically possible to ever measure the total amount in storage. This means that the amount of carbon sequestration has similar characteristics to a non-point pollutant in that it is difficult to know exactly how much there is and where it is.

Second, there are issues regarding the rate of accumulation. The amount of carbon that a given unit of soil will ultimately hold depends on the relationship between the rate of carbon addition and the rate of decomposition. This means that when a practice is changed resulting in an increase in carbon addition, the amount of soil carbon sequestered will rise until the rate of carbon decomposition matches the rate of addition. West and Six^[18] discuss this at length. What it means from a practical standpoint is that given a new adoption of a sequestration-enhancing practice, a change in sequestered carbon will accumulate for a while but then reach some sort of new equilibrium. West and Post^[19] review experimental data on tillage system changes and indicate that carbon accumulation generally occurs for somewhat less than 20 years with longer time periods for other sorts of changes. Furthermore, for all practices, they examine the rate of sequestration addition eventually falls to near zero. This means that one cannot rely on continual and constant levels of long-term annual soil carbon sequestration additions unlike is the case with manure management methane.

In addition, most actions that increase soil sequestered carbon have the characteristic that if the action is reversed (i.e., no till is discontinued) the soil carbon is released relatively rapidly. This then means that the sequestration level under most practices will continue for a while but then will approach a zero annual increment. It also means that the practice must be maintained perhaps at a cost. To our knowledge, the only exception to this involves biochar where the form of the carbon involved is highly stable in the soils and is not subject to practice reversal plus does not saturate nearly as fast. See, for example, the book by Lehmann and Joseph^[20] for discussion. Kim, McCarl, and Murray^[21] show in the face of this that carbon prices for sequestration are likely to be discounted by the market.

Third, sequestration is heterogeneous across different places depending upon physical and climate characteristics with the effects of practices highly dependent on local conditions. This means that it is difficult to know exactly how much one would get from a particular practice change at a place without some kind of local study.

Fourth, agricultural production in general is uncertain between years and so will be the rate of carbon addition to the soil. Furthermore, the spatial dispersion and heterogeneity bring about uncertainty. Smith et al.^[6] classify uncertainty as having two components: mechanism uncertainty and measurement uncertainty. The mechanism uncertainty reflects the complex biological and ecological influences on the rate of sequestration while the measurement uncertainty involves the difficulty of estimating exactly how much is accumulated. Such variability can be reduced with the use of spatially diversified sites.^[22] Kim and McCarl^[23] indicate that a contract containing widespread portfolio of soils over space and time exhibits substantially less variation in carbon accumulation.

Fifth, there is producer risk issue where, for example, once a practice is undertaken, there may be some good reasons to abandon it. For example, use of no till may need to be discontinued at least temporarily, if a large weed infestation occurs and/or critical herbicides used in weed control become ineffective. This frequently leaves agricultural producers desirous of leasing rather than selling carbon (see the discussion by Bennett^[24]).

Sixth, GHG offsets are often multi-GHGs (carbon, methane, and N₂O) in nature involving a complex chain of potential actions. For example, Schlesinger^[25] criticizes justifying actions based on soil carbon sequestration alone when they also involve added emissions in terms of other gases. He illustrates this point in the case of nitrogen fertilization and argues that the N₂O emissions coming from increased fertilization more than offset the sequestration additions. Moreover, the net GHG impact of stimulating soil sequestration may also alter fuel use and fertilizer needs altering emissions of fossil fuel-based emissions and those involved with fertilizer and pesticide manufacture. This means complete accounting across all gasses likely using life cycle analysis-based techniques^[26] are needed rather than concentration on on-site soil carbon only.

Seventh, cobenefits are involved where actions to manage soil carbon sequestration can create ancillary benefits plus increase willingness to pay for projects.^[27,28] For example, actions to increase soil sequestration mitigation can reduce erosion and runoff, improve biodiversity, and improve water quality. Elbakidze and McCarl^[9] argue that these should be considered carefully as there are cobenefits from alternative forms of GHG mitigation and just focusing on those involved with soil-related actions ignores benefits from other strategies. In a case study, they find the air quality cobenefits from reduced coal usage are as large as the benefits of expanding soil sequestration. Furthermore,

they indicate that it is costly to fully assess cobenefits across a wide variety of strategies.

Market demand factors

There are also a number of considerations on behalf of those purchasing carbon offsets—the demanders. The Kyoto Protocol, which is one of the principal documents that describes desirable features of a carbon trading market, identifies the characteristics of key GHG offsets. In particular, it raises additionality, permanence, leakage, and uncertainty. There are also concerns regarding transaction costs.

The concern about additionality involves whether or not the GHG content of the atmosphere is in fact reduced when one purchases a soil carbon offset. Basically the Kyoto Accord recommends only paying for practices that generate GHG offsets that are on net additional to the offset that would have happened in the absence of the payment. This raises the broad issue of a baseline where one needs to have a reasonable estimate of what the carbon sequestration in the soil would have been in the absence of the payment^[29–31] and then only pay for the incremental amount. Moreover, baseline establishment can be difficult. The adequacy of baseline determination has been known to cause the failure of suggested mitigation approaches as reviewed in Millard-Ball and Ortolano.^[32] There have been proposed rules for additionality, which in cases preclude practices that are already in use in the region. For example, the commonly discussed financial or investment additionality concept requires that the activity generating the purchased offsets to not be financially viable without the carbon payments.^[33–35]

The additionality situation becomes complex when there are existing uses of the practice in the region both in terms of those using the practice wishing to be paid for their prior good acts (see the discussion below) and in terms of incentive design. Additionality may well lead to a discounted price for soil carbon (see the exploration in Smith et al.^[36]). There is also the question of diminished incentives, if for example one reduces the payment by say some proportion, which is an estimate of the non-additional amount (see Feng^[37] for investigation). Some of the schemes such as that under the CCX and the one in Alberta do not require prior land use history and thus could have additionality problems. Anecdotal in talks, we have heard that their participants were dominated by people who were using conservation tillage before the beginning of the payments.

The concern about permanence involves whether once soil carbon is paid for that it, in fact, remains sequestered in the soil forever or whether there is some sort of limited term to the contract in the form of a lease. This arises since, for example, the actions reducing tillage intensity may well cause an increase in sequestered carbon, but the increases in tillage intensity would lead to a release of the sequestered carbon. Farmers may also wish to guarantee sequestration

only (providing a lease) for a given amount of time as indicated by Bennett.^[24] This, however, means that at the end of that time the purchaser would have to go and buy additional carbon from some other source. Hence the mitigation effects in the agricultural sector are not necessarily permanent, and some form of a grading standard or price may be needed to reflect actions to secure carbon for a longer duration. Kim, McCarl, and Murray^[21] investigated this issue and found that the permanence discount for soil carbon can be high.

The concern about leakage refers to whether emission reduction efforts from adopting sequestration enhancing or emissions reducing practices might be offset if they reduce conventional crop production and in turn stimulate production outside of the project region through the marketplace (as discussed in Murray, McCarl, and Lee^[38]). For example, replacing corn with perennial energy crops may well reduce net emissions but can cause emissions increasing land use change elsewhere.^[39,40] Certain studies have shown that leakage can be significant but various in sectors. For example, Wear and Murray^[41] show substantial leakage regarding displaced timber harvest but Murray, McCarl, and Lee^[38] indicate that it is likely small for tillage-induced soil carbon.

The uncertainty concern involves the supply uncertainty considerations discussed above coupled with the fact that potential purchasers face penalties if they are out of compliance. Sometimes these penalties can be substantial. For example, when the U.S. sulfur dioxide trading scheme was operating, it contained a penalty for excess emissions above the permits held that exceeded 10 times the trading price. This creates a desire to buy offsets that can be safely relied upon to exceed the regulatory commitments. This likely means that credits bought would not represent the amount that would occur on average but rather reflect a safety margin in the form of an uncertainty discount. Kim and McCarl^[23] provide further justification and a procedure for computing such a discount and show that it can be reduced with broad portfolios over time and space. The carbon trading schemes such as those in Alberta, the CCX, and Australia mention such safety margins and/or were designed with conservative permitted amounts reflecting consideration of the uncertainty factor.

Finally, we come to transaction costs. This is the amount of money needed to carry out the trades and is a gap between what the ultimate purchaser pays and the offset producer receives. Transaction costs have been identified as one of the greatest hurdles for tradable permit systems.^[42] Their magnitude will have important consequences for the ability to trade an item. Cases have arisen where transaction costs have caused markets to fail.^[43] In the soil case, the transaction costs largely would deal with assembling the group of producers to sell the contract, project design, measurement and monitoring of sequestration volume search and negotiation, approval, project management, enforcement, and insurance.^[44,45]

Measurement and monitoring costs arise from compliance and practice continuation verification. The measurement costs will mainly involve the costs of some mixture of aerial sensing, on-site measurement, and modeling.^[6] Several studies have examined the magnitude of these costs, yielding some disparity in conclusions regarding their size.^[22,46,47] Such costs generally vary with the price of carbon credits, the quantity of carbon sequestered, the extent of the sequestration area, and methodological advances along with other factors.^[6,22] Millard-Ball and Ortolano^[32] argue that the costs would be increased by the expenditures on preparing the measurement and project design document plus emission monitoring.

Assembly costs may be the larger item. Alston and Hurd^[48] estimate that the transaction costs of administering the farm program ranged from 25 to 50 cents for each dollar distributed. McCann and Easter^[49] find transaction costs of the magnitude of 38% of total costs or over 50% of direct payments. Need for a contract for an annual offset of 100,000 tons of carbon dioxide from farms would involve over 200 U.S. farmers in a group (assuming 1 ton of carbon dioxide per acre per year and average farm size of 400 acres) and thousands of small farmers in developing countries imposing a likely costly set of transaction costs that might preclude small farms.^[44,47]

Higher transaction costs could well prevent the entrance of smallholders.^[6] Butt and McCarl^[50] suggest that multi-year contracts with the same group of carbon credit suppliers might help to reduce the transaction cost and in turn to keep the overall compliance costs low; moreover, bundled projects and payments could also reduce these costs.^[47]

Attitudes

There are also a number of attitudes and opinions that influence the possibility of soil carbon trading. The ones we feature here involve opposition to soil carbon sequestration and feelings about market structure, which are not consistent with some of the Kyoto-based concerns.

One set of attitudes involves opposition to using biological carbon sequestration. Doubts based on permanence and uncertainty issues have been expressed by some scientists^[51] and a number of particular European environmental groups.^[52] Another aspect involves the feeling that use of sequestration legitimizes fossil fuel use and that emissions must be the focus of control.^[53]

In terms of feelings about market structure, there are two fundamental issues. The first is reflected in the position taken a few years back by a number of farm groups that all sequestration should be paid for regardless of the land-use history including preprogram, “early adopters.” However, given the “saturation or approach to zero” findings discussed above, it is clear that the land use history determines the volume of sequestration and whether or not sequestration gains will be realized. Paying early adopters

under a strict Kyoto Protocol interpretation would not meet the additionality test.

Second, there is the opinion that farmers are unwilling to make long-term commitments as reflected in Bennett^[24] and that therefore short-term, lease-like, contracts for sales need to be used. That opinion flies in the face of the buyers' desire for permanence. There is also an allied desire for farmers to avoid long-term obligations against their farming practices and property. For example, a farmer may undertake soil carbon sequestration-enhancing practices under a 100 year contract and then in turn sell the land to someone else who must maintain those practices perhaps in the absence of carbon payments if saturation has occurred. Again this favors leasing and is in conflict with permanence desires. Marland, McCarl, and Schneider^[29] discuss this and other property rights issues.

SOME ACTIONS

We have now reached nearly the end of the entry with the findings that the general level of carbon trading has been somewhat lower than expected, the level of agricultural trading has been a lot lower than expected, and that fully Kyoto compliant soil carbon trading has been virtually nonexistent with the only trades we are aware of (CCX and Alberta) potentially having large additionality concerns. This raises the obvious question that if we wish to trade soil carbon for money what sort of actions might we undertake. There are likely a wide number of non-mutually exclusive alternatives, several of which are discussed here.

Approach one: Own the flaws. Given the vocal resistance to soil carbon (based on permanence and uncertainty), it may be best if scientists and offset producers fully acknowledge that soil sequestration is not a permanent item that is available in a certain quantity. In turn to address the permanence concerns, soil carbon producers might offer contracts for non-permanent leased items for lower than market prices. This would be accompanied by the argument that there is value in temporarily providing soil carbon credits but with recognition that this value will not be on par with permanent offsets (such as burning a methane emission—see discussion in Smith et al.^[36]). This can also be accompanied by the argument that carbon is a bridge to the future as mentioned in Marland, McCarl, and Schneider,^[29] and delays the amount of time at which the offset purchasers will have to make technological changes allowing time for innovation. Also to address uncertainty, soil carbon producers could develop contracts that contain carbon from widely spatially dispersed sequestration sites for a cumulative amount over multiple years to help manage the uncertainty (note Kim and McCarl^[23] show such contracts have the potential to greatly reduce the uncertainty). Producers would also be well served if evidence could be assembled that documents the narrowing of uncertainty under spatial and temporally diverse contracts in field

observations. Finally in the contracts, it would well be worthwhile to advocate a squaring up after some period of time to compare the actual level of increase in sequestered carbon versus that projected allowing producers to potentially gain back some of the payments for the safety margin. Also one may include offsets from other groups like cattle feeders to create a more diversified and lower risk portfolio.

Approach two: Address additionality. Prior land use history is an important factor in determining the volume of sequestration plus the total cost of the program. In particular, if all practice users are to be paid then the program may well cost more per unit carbon than under alternative offsets diminishing the attractiveness of soil carbon. Soil producer groups either need to reach an agreement with the purchasers where the purchasers are willing to pay an excess amount for the net amount sequestered carbon or somehow include a *prior* land use history requirement in the contract. Experience seems to indicate that the trading market acceptance of excess payments is somewhat unlikely and this certainly lowers the desirability of soil carbon to the purchasers. Yet this seems to be the position of most farm groups and needs to be recognized by both sides in a contracting discussion. Personally we doubt that an approach of ignoring the prior land use additionality concern can be viable but perhaps negotiations can make it work. Naturally an alternative is to only allow payments for those newly switching practices and developing procedures to document and guarantee that.

Approach three: Design-phased carbon amounts for practices in contracts. While economic studies such as Mooney et al.^[22] show that payment per ton is more economically efficient than payment for practice adoption, they ignore transaction costs. In implementation, programs such as the now defunct CCX put in a constant amount that they would pay for practices across all land in wide geographic areas. This amount is not the amount that will be sequestered each year, as it is likely to be larger at the beginning of the practice and smaller after the practice is fully mature. Perhaps a phased amount should be developed giving a tonnage for the first 5 years, a new practice is in use and a different amount for the second 5 years, then yet another amount for the third 5 years, and so on. Perhaps there should also be a maintenance payment after the practice saturates. Developing this more complex carbon schedule would more realistically represent what was happening and perhaps reduce resistance to trading soil carbon. Including the maintenance payment would also address some of the permanence issue and give farmers a stake in maintaining the carbon allowing longer term contracts.

Approach four: Figure ways to manage the transaction costs. While we believe the assertions like those in Mooney et al.,^[22] which indicate that the measurement and monitoring costs may be small, we also believe that the assembly, funds distribution, compliance monitoring, and

other costs could be quite large. In the crop insurance case that has a lot of similarity, local aggregating agents keep 25% of the money and pass 75% on to the crop insurer. This implies that the transaction costs could be large and perhaps groups need to evolve strategies to manage this like using farm cooperatives, farm groups, or public agencies. On the other hand, we would note that the Iowa Farm Bureau did this under the CCX and was heard to state that the costs were too large relative to the 10% fee they were charging. This was in part due to low carbon prices but still shows the need to engage a cheaper assembly process. A pure private market solution is likely to charge upward of 25% in transaction costs and cause a pretty large wedge. Furthermore, for smallholders in developing countries these costs could be very large precluding participation.

Approach five: Look for ways to sell carbon outside of a trading market. Practices like tillage conversion or grassland establishment that are carbon sequestering have been the recipients of payments under environmental programs such as the conservation reserve program or various soil erosion programs. Perhaps it would be best to advocate the inclusion of carbon payments in such practice subsidy-based programs and not try to trade carbon.

Approach six: Advocate grading standards in the sale of carbon much like we have them for other commodities. Agricultural commodities have involved grading standards on broken kernels and foreign matter or moisture for a long time. Certainly alternative offset forms that could enter the carbon market have different characteristics that could be differentiated by grades. For example, if methane is captured out of a manure lagoon and immediately combusted generating electrical power, then the methane can be metered and this is one-time permanent reduction in methane emissions with the methane destroyed, so it cannot be released in the future. As such, it has more value to one purchasing a carbon offset and that represents an uncertain amount of carbon sequestered in the soil that could be rereleased to the atmosphere if the practices were reversed. Thus, for example, soil carbon might fit into one grading class and could trade but at a discounted price relative to other options.

Approach seven: Advocate forms of climate change control. Soil carbon certainly will not trade in markets unless there is a market-making binding cap or substantial value to participating in a voluntary market. Perhaps those wishing to trade soil carbon should advocate the need for climate change mitigation and the value of trading as a means of lowering costs and stimulating innovative solutions. It is interesting that while many in the farming sector doubt the human influence on the climate, they also may be advocates of trading carbon for money. A widespread consistent mitigation advocacy approach would enhance the chances of trading.

Approach eight: Adopt a position that the seller will assume shortfall liability. One could facilitate trading by creating contracts with stronger guarantees of carbon

retention and carbon amounts. This could involve entering into more binding agreements regarding non-reversible practices and by using uncertainty discounts and thus assuring that the carbon being sold is in fact being sequestered. This could also be guaranteed with, for example, an offer by the sequestration producer to assume any penalties incurred by the buyer under shortfalls in compliance. In turn, individual farmers could choose whether or not they are willing to bear the risks when they decide whether or not to participate in the program.

Approach nine: Band together with other elements of agriculture to advocate an expanded agricultural role. Here one would advocate for a place for agriculture in trading. This could be coupled with documented arguments that agriculture provides a low-cost alternative relative to say the cost of emissions control in fossil fuel-using activities.

CONCLUDING COMMENTS

Trading soil carbon has not been an extremely widespread venture to date and likely will not be in the future unless different approaches and advocacy positions are taken. We have discussed the main reasons for the small role. This involves a lack of widespread markets especially in countries like the United States, the common lack of inclusion of agriculture in trading schemes, the inconsistency of soil carbon characteristics with purchasers' desires as manifest in the Kyoto Protocol, and producer/purchaser/environmental group attitudes. For trading soil carbon to become greater, we believe first that an active GHG offset trading market needs to be accessible to the producer and second that some different strategic approaches to the advocacy of and contractual basis for soil carbon trades need to arise.

Abstract

The process of exchange of air between soil and the atmosphere, called aeration, is important to plant growth because it maintains oxygen (O_2) in the root zone at the level needed for root and microbial respiration. The O_2 in soil air also governs the chemical reactions that provide the necessary conditions for oxidation of reduced elements (Fe^{2+} and Mn^{2+}), which may otherwise be toxic to plant growth. The air circulation in and out of soil matrix also regulates the temperature of the soil. In addition to plant growth, soil air composition alters the production and emission of trace gases [e.g., methane (CH_4) and nitrous oxide (N_2O)].

INTRODUCTION

Soil air differs from atmospheric air in several respects. The composition of soil air varies greatly from place to place in the soil matrix, as plants consume some gases and microbial processes release others. The carbon dioxide (CO_2) content in soil air is much higher and the oxygen (O_2) content is much lower than the atmospheric air. The soil air is also relatively moister than the atmospheric air. The amount and composition of soil air is determined by the water content of soil unless soil is very dry. The O_2 content in a well-aerated soil is higher than that of a poorly aerated soil. The latter has higher concentrations of CO_2 , methane (CH_4), and nitrous oxide (N_2O) than atmospheric air. A soil is considered healthy if the air-filled pore spaces are about 50% of the total porosity and composition of the soil air is similar to that of atmospheric air.

MEASUREMENT OF SOIL AERATION

Measurement of soil aeration involves assessing: 1) composition of soil air and 2) rate of diffusion of O_2 from atmosphere into the soil. Measurement of the relative concentrations of O_2 , CO_2 , and other gases in the soil air provides important information on the aeration and soil structure. Depletion of O_2 level content in soil air is a good indicator of the restricted gas exchange in the soil matrix. This method, although static, is better than the measurement of air volume alone. However, it requires extraction of a sample that is large enough to provide a measurement, but at the same time small enough to be representative. Another

drawback of this method is soil disturbance and contamination or mixing of air from the atmosphere. The measurement of depletion of O_2 or increase in CO_2 can be made both *in situ* or in a laboratory by gas chromatography technique which provides reliable measurements. The repeated measurements of O_2 concentrations in soil air without extracting a sample can also be obtained by electrode methods. The measurement of soil aeration is carried out at known or standardized soil water suction, at about 50 cm of water.

AIR PERMEABILITY

Air permeability is defined as the ease with which air enters or passes through a bulk mass of soil and has the dimensions of area (square liter). Air permeability of porous media is governed by both the convective transport and the diffusional transport of air. The convective transport occurs under a pressure gradient, whereas diffusional transport occurs due to the change in concentration gradients or the partial pressures of the various components of soil air. Under normal circumstances, both convection and diffusion processes occur simultaneously, provided the concentration and pressure gradients exist concurrently. The mass flow of gas is important when differences in pressure are due to the change in barometric pressure, temperature, or soil water content. Measurement of air permeability of soil is important because it provides valuable information on: 1) soil structure; 2) pore size network; 3) changes in soil structure due to land use and land management practices; and 4) saturated hydraulic conductivity of soil.

Table 1 The measured average gas permeability at highest soil air content for a range of soil water suction interval with respect to clay content of soils.

Clay (%)	k (μm^2)	Soil water suction (cm H_2O)
2.5	14.3	$16 > h > 100$
3.7–4.3	36.0	$10 > h > 500$
5.9	22.8	$50 > h > 500$
16	1225.0	$20 > h > 3000$
21–24	525.0	$10 > h > 1090$

Source: Adapted from Sabatier, Hess, et al.^[1]

Table 1 presents typical air permeability values measured on soil cores.^[2]

BASIC PRINCIPLE

According to Darcy's law for laminar flow (no acceleration along line of flow), velocity of a given fluid is proportional to the pressure difference and inversely proportional to the length of the flow path. Therefore, Darcy's law is applicable for the airflow through soils and air permeability (k_a) can be defined by the following relationship:

$$k_a = q\eta_a \frac{dx}{dp} \quad (1)$$

where q is the volume flux per unit area ($\text{L}^3\text{L}^{-2}\text{T}^{-1}$), η_a the dynamic viscosity of air ($\text{ML}^{-1}\text{T}^{-1}$), p the pressure of air ($\text{ML}^{-1}\text{T}^{-2}$), and x the distance in direction of flow (L).^[3] The dimensions of air permeability coefficient, k_a as L^2 , are similar to the intrinsic permeability of soil, and therefore, k_a is also referred to as intrinsic permeability of air.

MEASUREMENT OF AIR PERMEABILITY

The methods of measuring air permeability can be broadly divided into steady-state methods, unsteady state (or transient) methods, and acoustic methods.

Steady-State Methods

The steady-state methods are commonly categorized into i) constant pressure gradient method and ii) constant flux method.^[4] In constant pressure gradient method, air is blown across a soil core (or repacked soil column) at a constant pressure above the atmospheric pressure (Fig. 1), and the rate of flow of air at the inlet end of the soil core is measured. The constant pressure gradient method is suitable for soil cores at high water content. In constant flux method, a constant air flux is applied at one end of a soil core, and pressure difference across the

Fig. 1 Schematic of the apparatus to measure air permeability (k_a).

soil core is measured. The soil core is placed inside a chamber and is connected to a water manometer or a pressure gauge to measure pressure difference across the sample. The constant flux method is simple and straightforward and is useful for soils of low air permeability.

Conservation of moisture status of the core sample is an important requirement for air permeability measurement. The water content of the soil core is a function of the pressure difference between both air and water, and the pressure gradient between these two competing fluids should be equal in magnitude and direction. One of the methods is stationary liquid method,^[5] in which air flows upward and through the sample in response to a pressure gradient equal to that in a static liquid. The other method uses both fluids flowing with equal pressure gradient in any direction. The steady-state laboratory methods described till now are reasonably accurate and reproducible for disturbed or rock samples. The merits and demerits of air permeability measurement methods are given in Table 2.

Transient Methods

Transient methods are practical, rapid, economic, and easy to use. They can be employed for air permeability measurements both in the laboratory on soil cores and directly in the fields. They also require less volume of air to pass through the soil core or soil volume for a given permeability determination. The duration of the tests is shorter, and soil desaturation or drying is less as compared to the steady-state method. In transient *in situ* method (Figs. 2 and 3), one end of a soil core is connected to a close pressurized air tank and the other end is kept open.^[3] The rate of drop of air pressure in the tank is measured as the air flows out through the other end and is used to calculate the air permeability of soil.^[6] The field air permeameter has been modified to include a gas cylinder and a water manometer to replace the float.^[7] The apparatus is suitable for air permeability measurements *in situ*, on-site, and in laboratory on soil cores. Traditionally, air permeability calculations are made for isothermal conditions. However,

Table 2 Merits and demerits of air permeability measurement methods.

Steady-state laboratory method		Transient method		Acoustic method
Pressure gradient	Flux method	Core method	Field method	Field method
Constant pressure gradient	Constant flux	Drop in pressure in air tank	Drop in pressure in air tank	Reflection and transmission of audio frequency
Easy and simple	Constant flux and gradients are difficult to attain	Rapid and easy	Practical, rapid, economical, and easy	Rapid but requires skilled labor
Suitable for highly permeable soils	Suitable for less permeable soil	Suitable for both	Suitable for both	Suitable for homogeneous soils
Does not alter water content	Water content is altered	Does not alter water content	Does not alter water content	Does not alter water content
Disadvantage of airflow between soil and core	Disadvantage of airflow between soil and core	Disadvantage of airflow between soil and core	—	—
—	Soil shrinkage	—	—	—
Well developed	Well developed	Well developed	Well developed	Underdevelopment

air permeability can also be calculated for the nonisothermal conditions, arising due to temperature changes inside the gas cylinder.^[6]

Acoustic Methods

Sound reflected from a soil surface interferes with the incident sound and causes an interference pattern in the total sound field. If the acoustic properties of porous media are known, interference patterns can be modeled from theory of sound propagation. Analytic approximations for calculating the sound levels from outdoor sound sources on or near the ground in terms of acoustic properties of soil are available.^[8] For a homogeneous porous medium, these acoustic properties depend on the air-filled porosity of soil surface.^[9] The acoustic techniques involve the measurement of both the reflection and the transmission of audio frequency broadband sound by the soil. The sound reflection measurements give qualitative indications of relative air permeability. Sound transmission measurements are made by inserting a probe microphone at a given depth and keeping another vertically separated above ground. Theoretical predictions for homogeneous soils are fitted to the

measured reflection, and quantitative information on surface air-filled porosity and air permeability is obtained. The acoustic techniques have been validated on a series of trial plots for a variety of soils and have been found within 10% of those obtained conventionally and have shown a potential for the measurement and monitoring of management induced or seasonal changes in soil surface properties.^[2]

CONCLUSION

Air permeability is sensitive to changes in soil structure resulting from different land use and soil management practices. Air permeability of soils is recognized as an important parameter for soil aeration and contaminant remediation techniques and is fundamental to our understanding of environmental problems in vadose zone (or root zone

Fig. 2 Schematic of an air permeability apparatus on soil cores for transient method.

Fig. 3 Schematic of an *in situ* air permeability apparatus for transient method.

Source: From Grover.^[10]

depth). Knowledge of air-filled pores, pore size distribution, tortuosity, air permeability, and their variation along the cross section or depth is important to describe aeration, structure, and compaction of the soil. Air permeability can be measured both in the laboratory and on the field by steady-state as well as transient methods. Transient methods are better than steady-state methods, as they are more practical, rapid, economic, and easy to use.

University of Miskolc, Miskolc-Egyetemváros, Hungary*

Abstract

The fraction of the incident radiation that is reflected from the surface is called the albedo. Albedo plays a major role in the energy balance of the earth's surface, as it defines the rate of the absorbed portion of the incident solar radiation. Soil albedo is a complex feature, which is determined by many soil dependent and independent (environmental) characteristics. The process that results in the reflected radiation is called reflectance, whereby the energy of radiation is reradiated by the chemical constituents (e.g., atoms or molecules) of the surface layer approximately half the thickness of wavelength. The portion of solar radiation not reflected by the earth's surface is absorbed by the soil or the vegetation, which interacts with the incident radiation. The absorbed energy can increase the soil temperature or the rate of evapotranspiration from the surface of the soil–vegetation system. Some of the energy that is absorbed and transformed into heat is reradiated at a longer wavelength than the incoming radiation. That is why the peak terrestrial radiation occurs in the infrared spectrum, while the peak incident radiation occurs in the blue–green portion of the visible spectrum.

INTRODUCTION

The albedo value ranges from 0 to 1. The value of 0 refers to a blackbody, a theoretical media that absorbs 100% of the incident radiation. Albedo ranging from 0.1 to 0.2 refers to dark-colored, rough soil surfaces, while the values around 0.4–0.5 represent smooth, light-colored soil surfaces. The albedo of snow cover, especially the fresh, deep snow, can reach as high as 0.9. The value of 1 refers to an ideal reflector surface (an absolute white surface) in which all the energy falling on the surface is reflected. The mean albedo of the earth system is 0.36 ± 0.06 (Table 1).^[1]

FACTORS AFFECTING ALBEDO

Albedo varies diurnally and seasonally due to the changing sun angle.^[2,3] In general, the lower the sun angle, the higher the albedo. Besides the sun angle, many of the surface characteristics have large impact on the albedo. The most significant factors affecting the soil albedo are the type and condition of the vegetation covering the soil surface, soil moisture content, organic matter content, particle size, iron oxides, mineral composition, soluble salts, and parent material.^[4]

The type and the condition of the vegetation have a strong impact on the surface albedo. Forest vegetation with multilevel canopy has a low albedo because the incident radiation can penetrate deeply into the forest canopy where it bounces back and forth between the

branches and leaves and get trapped by the canopy.^[5] The albedo for grassland and cropland ranges between 0.1 and 0.25.^[6–9]

Changes in soil moisture content change the absorbance and reflectance characteristics of the soil. Increase in soil moisture content increases the portion of the incident solar radiation absorbed by the soil system. This relationship is well known and used for soil color differentiation when the Munsell color chart is used. The colors of dry and moist soil samples are always different. The higher the soil moisture content, the darker the color and the lower the albedo. However, this relationship is valid only for soil moisture contents up to the field capacity. Beyond field capacity, the increase in soil moisture content does not darken the color anymore but starts building up a water sheet on the aggregate surface, creating a shiny and better reflecting surface, which increases the reflectance and thus the albedo. This phenomenon is the major reason for differences in the albedo among soils of different textural classes. Clayey soils can maintain high moisture content in the presence of water supply, while the sandy textured soils drain and dry out much more rapidly. Due to the differences in the resulting soil moisture content between the texture classes, there are differences in the reflectance and absorbance characteristics and so in the albedo (Fig. 1).

Surface roughness defines the type of reflection. Shiny, smooth surfaces, like water body, plant leaves, or wet soil surfaces may be near-perfect, specular reflectors, which may reflect well and show relatively high albedo for lower sun angles. Rough surfaces represent

Table 1 The approximated ranges of albedo of natural surfaces.

Natural surface types	Approximated albedo
Blackbody	0
Forest	0.05–0.2
Grassland and cropland	0.1–0.25
Dark-colored soil surfaces	0.1–0.2
Dry sandy soil	0.25–0.45
Dry clay soil	0.15–0.35
Sand	0.2–0.4
Mean albedo of the earth	0.36
Granite	0.3–0.35
Glacial ice	0.3–0.4
Light-colored soil surfaces	0.4–0.5
Dry salt cover	0.5
Fresh, deep snow	0.9
Water	0.1–1
Absolute white surface	1

lower albedo values, especially when sun angle is low and the shading effect lowers the reflection. There are measurable differences in the surface roughness among soil textural classes. Fine-textured, dry soils with small particle size produce high albedo due to relatively

Fig. 1 The higher the moisture content the lower the reflectance throughout the visible and near-infrared region, especially along the water absorption bands at 1.4 and 1.7 μm . Notice the differences in the reflectance characteristics between the clayey and sandy soils.

Source: From Hoffer.^[10]

smooth surface. However, clayey soils are often wet, and soil moisture absorbs the incident radiation and decreases albedo. Conversely, dry, coarse-textured soils with relatively large particles (sand grains) reflect the larger portions of incident radiation than clayey soils.

Surface color is determined by the interaction of the surface material with the visible spectra of the incident solar radiation. Soil color is a differentiating factor in all the soil classification systems. It reflects many of the most important soil physical and chemical characteristics. One of the most significant coloring agents of the soils is the soil organic matter content. Soil organic matter content increases the absorbance of the soil. Thus, the higher the organic matter content, the lower the albedo. Iron oxides increase the reflectance in the red portion of the spectrum while causing a decrease in the blue-green and infrared portion. Salt crust on the surface increases the albedo dramatically. That is why mapping of salt-affected area with remotely sensed images is a very powerful tool for soil surveyors.

MEASUREMENT OF ALBEDO

The theoretical concept of measuring albedo is simple. A radiation sensor (pyranometer) is pointed upward to measure the incident radiation and then quickly flipped downward to measure the reflected radiation. For deriving the albedo, the quantity of the reflected radiation has to be divided by the one for the incident radiation. In fact, the actual measurement of surface albedo under natural condition is rather complex. The problem is threefold. Firstly, the incident radiation does not only come from the radiation source directly but also from diffused light from other directions. Secondly, the reflector surfaces do not reflect equally in all directions, and thirdly, the sensors gather light only from a small range of angles. Thus, our measurements of reflectance are only samples of the bidirectional reflectance distribution function. Albedo is often defined as an overall average reflection coefficient of an object. More precisely, the terms of spectral and total albedo are differentiated. The spectral albedo refers to the reflectance in a given wavelength, while the albedo is calculated as an integral of the spectral reflectivity times the radiation, over all wavelengths in the visible spectrum. A good estimation of the surface albedo can be done using clear-sky satellite measurements.^[11]

CONCLUSION

Albedo measures the overall reflectance of the surface. It provides lots of useful information about the soil system and helps to better understand the soil energy balance. But different wavelengths of sunlight are normally not equally reflected, which gives rise to a variable color of

surfaces and differences in reflectance of certain wavelengths due to differences in physical or chemical characteristics of the soil surface. Differences in soil albedo can be measured with radiometers.

Alfisols

Rienk Miedema

Department of Soil Science and Geology, Wageningen University, Wageningen, the Netherlands

Abstract

Alfisols occur almost everywhere, provided that conditions suitable for clay illuviation are met, either presently or in the past. The subdivisions of Alfisols are based on climate. Medium-textured, decalcified, weakly acidic parent materials like loess and glacial deposits provide suitable conditions for clay illuviation, while the leaching of basic cations has not progressed too far and a high cation exchange capacity is maintained.

INTRODUCTION

The definition^[1] of the soil order of Alfisols is as follows: Soils do not have a plaggen epipedon and have either 1) an argillic or kandic horizon (base saturation 35% or more) or a natric horizon, or 2) a fragipan with clay films of thickness 1 mm or more in some parts. The argillic, kandic, and natric horizons are formed as illuvial subsurface horizons, characterized by a significantly higher percentage of clay than the overlying eluvial horizon. The fine fraction of clay is strongly involved in the clay illuviation process (the ratio of fine clay to total clay is the highest in the argillic horizon).

The argillic and the kandic horizons differ because the kandic horizon has over more than half its thickness an apparent cation exchange capacity (CEC) of 16 cmol(+) or less per kg clay.

The natric horizon is an argillic horizon with: 1) columnar or prismatic structures in its upper part with or without uncoated silt and sandgrains in the top of the horizon and 2) an exchangeable sodium percentage of 15 or more, a sodium (Na) adsorption ratio of 13 or more in the upper part of the horizon, or more exchangeable magnesium plus Na plus exchangeable acidity in the upper part of the horizon. Alfisols, distinguished on the basis of a fragipan (firm rupture resistance and slaking of water-submerged air-dry fragments), also show clear evidence of clay illuviation,^[2] but the relation between fragipans and argillic horizons is controversial.^[3–5] Alfisols are very reviewed.^[6] The objective of this short communication is to reflect, in a general way, on the (palaeo)environmental conditions under which clay illuviation, the main soil-forming process in Alfisols, takes place. The areal extent and geographical distribution of Alfisols are summarized.

THE CLAY ILLUVIATION PROCESS

Particulate dispersed (fine) clay is liberated in the surface soil, is transported down the profile, and accumulates

(precipitates) in the subsurface horizon. Which conditions promote the liberation of dispersed (fine) clay from (micro)-aggregates in the surface soil?

These conditions can be considered from a (bio)physical and biochemical point of view. The clay mineralogy is also of importance: Smectitic clays disperse to finer clay particles than kaolinitic clays (as in the kandic horizon).

From the (bio)physical point of view, the moisture content of the soil material is important. Suddenly wetted dry aggregated soil material may experience “air explosion.” The wetting front proceeds to the center of the dry aggregate, the trapped air is compressed, the aggregate explodes, and fine and coarse material is released. The porosity and chemical characteristics of the original aggregates determine whether air explosion happens. Very porous aggregates do not experience air explosion. Soil material with many Ca^{2+} or Al^{3+} bonds forms stable aggregates that do not produce fine clay upon air explosion.

The ratio of water to solid is important.^[7] When the water content is extremely high, this may promote the liberation of fine clay. From the (bio)chemical point of view, aggregate stability/clay flocculation is important. Soil material with a high percentage of exchangeable Ca^{2+} or Al^{3+} clay remains flocculated even with extremely high ratios of water to solid. Humic substances play a role in the liberation of fine clay, related to the clay mineralogy.^[8,9]

It is possible to indicate pH ranges in the soil, where liberation of fine clay is possible.^[10–12] In soils with a pH below 5, the amount of Al^{3+} in the soil solution and the amount of exchangeable Al^{3+} are so high that the clay remains flocculated.

In soils with a pH of 7–8, the amount of Ca^{2+} in the soil solution and on the exchange complex is so high that the clay remains flocculated. In soils with a high pH (8.5 or more), Na^+ is strongly dominant and the liberation of dispersed fine clay is promoted due to a very extended electric double layer (natric horizon).

Hence, the prerequisites for soils to become Alfisols are as follows: 1) decalcification of originally calcareous parent

materials; 2) not very acidic parent materials; and 3) strongly alkaline parent materials.

Downward transport of the fine clay occurs as laminar flow with water along the pore walls.^[13,14] Turbulent flow moves coarser particles downward.

Accumulation (precipitation) of the liberated (fine) clay with adsorbed iron (Fe) may occur through a number of mechanisms.

Chemically, a calcareous subsurface layer (Fig. 1B) forces the fine clay to flocculate and precipitate on the pore wall.

Stratification may trigger the accumulation of the (fine) clay at boundaries of finer and coarser textured soil materials. In sandy soils, this leads to the characteristic “banded B horizons” with bridges of fine clay between the sandgrains.^[16,17]

Water absorption in a dry subsoil from pores may also prompt precipitation of fine clay on the pore wall.

Recognition of Illuvial Clay

Macromorphologically, clay coatings in pores or on pedfaces, distinguished by their more shiny appearance, are noted in the profile description. To judge the composition of the coatings with the naked eye or with a hand lens is difficult.

The accumulation of fine clay in the argillic horizon leads to the parallel arrangement of clay particles (continuous orientation) and distinctive optical properties such as strong birefringence and extinction phenomena (Fig. 2A and B) in thin sections (30 μm thick) of undisturbed soils.^[19,20]

In macroscopically identified argillic horizons, and sometimes in micromorphologically, very little clay coatings are observed.^[21,22] Recognizing and counting

fragments of clay coatings and distinguishing between illuvial clay coatings and stress coatings are not always easy. Strong swell–shrink activity of smectitic clay in certain soils leads to argillic horizons “without clayskins.”^[23]

Quantification of Clay Illuviation

In micromorphological quantification of clay illuviation,^[15,24,25] different trained operators obtain different results on the same samples (coefficients of variance of 50%).^[24,25]

Volume percentages of micromorphologically illuviated clay in argillic horizons range from about 1 to 20%. Well-developed argillic horizons in loess typically contain 4–7% illuviated fine clay micromorphologically (Fig. 1A and B).

Pedological Translocations/Transformations of Clay Coatings

The accumulated fine clay is present as films coatings or pore walls. Subsequent biological activity may translocate fragments of the coatings into the groundmass of the soil.

The accumulation of clay in the subsurface horizon may lead to problems with the hydraulic conductivity in that horizon. Redox processes (pseudogley) in the upper part and along cracks and pores in the argillic horizon lead to degradation features^[3,26,27] in the argillic horizon: clay coatings (partly) covered with Fe/manganese precipitates with less Fe content or with grainy clay coatings (clay destruction) by ferrololysis.^[28] In Mediterranean^[29] and semiarid areas, argillic horizons are found with clay illuviation and subsequent recarbonation from eolian dust (secondary calcite coatings covering fine clay coatings).

TIME OF FORMATION OF THE ARGILLIC HORIZON

The optimum conditions for the occurrence of clay illuviation (argillic horizon) are much disputed. One school of thought considers clay illuviation to occur in

interglacial periods, such as the Holocene period.^[4,19,30–32] Widespread semideciduous and mixed broadleaf–coniferous natural forest vegetation (through humic acids in their topsoil) is thought to create conditions optimally suitable for the liberation of fine clay in the topsoil.

Fig. 3 Geographical distribution of Alfisols.

Source: U.S. Department of Agriculture, Nature Resources Conservation Service, Soil Survey Division, World Soil Resources, © U.S. Department of Agriculture.

Another school of thought^[33–36] considers the optimum period for clay illuviation to occur at the end of a glacial period or at the beginning of an interglacial or interstadial period. Following rapid Late Glacial decalcification of originally calcareous parent materials, the conditions for liberation of fine clay occur in the melting topsoil. This topsoil (active layer) is freeze-dried in frozen conditions, and the melting of ice lenses produces sudden wetting, air explosion, and liberation of fine clay.

Relict argillic horizons occur in Late Pleistocene loess soils below tidal marshes (submergence due to postglacial sea level rise) in Maryland.^[37]

The Late Glacial conditions are also conducive for the formation of a fragipan or fragic characteristics^[34,38] in loess and glacial till in North America,^[2] Western Europe,^[34] and Russia.^[18] Distinction is made between argillic horizons and paleo-argillic horizons.^[39] Paleo-argillic horizons are not associated with soil-forming conditions.^[40–42]

GEOGRAPHICAL DISTRIBUTION AND AREAL EXTENT

Alfisols (total areal extent of which is 9.6% of the ice-free land surface of the earth) occur almost everywhere, provided that conditions suitable for clay illuviation are met, either presently or in the past (Fig. 3). The subdivisions of Alfisols are based on climate (temperature and precipitation). Suborders comprise the cryalfs of Arctic areas, the udalfs of temperate humid areas and the ustalfs and xeralfs of semiarid and/or dry areas. A large proportion of the Alfisols occurs in the temperate and Mediterranean zone. Medium-textured, decalcified, weakly acidic parent materials like loess and glacial deposits provide suitable conditions for clay illuviation, while the leaching of basic cations has not progressed too far, and a high CEC is maintained.

Landscape position (degradation of Alfisols) is accommodated in the suborder of the aqualfs.^[43,44]

Abstract

Allophane is a nanospherical aluminosilicate, the aluminum (Al): silicon (Si) ratio of which can range continuously from values of 2 to 0.9. It forms in several different environments but is most characteristic of parent materials influenced by volcanic tephra, where it is often associated with the related nanotubular aluminosilicate imogolite. The structure of both these materials is based upon a rolled octahedral Al (gibbsite-like) sheet, with individual orthosilicate tetrahedra bonded to the interior; at progressively higher Si contents, the silica is polymerized and the gibbsite sheet may be fragmental or incomplete. The hollow nanoball structure of allophane influences its physical properties, giving it a low bulk density, high water-holding capacity, and high sorption capacity for organic matter, phosphorus, and other nutrients. The unique and distinctive properties of allophanic soils require specific management practices and result in the creation of the Andisol soil order.

INTRODUCTION

Allophanes are poorly crystalline nanoscale aluminosilicates that are especially prevalent in soils formed from volcanic ash. They are frequently found in association with imogolite, most commonly as products of the weathering of volcanic tephra. Allophane minerals impart unique chemical and physical properties to soils in which they are a predominant mineralogical component, and those properties have implications for management of soils. The influence of allophanes on soil behavior is largely responsible for the development of the Andisol soil order, highlighting the importance of allophane minerals in defining the chemical and physical properties of soil and therefore the soil's response to management. The following discussion will focus on the structure and resulting properties of end members, as defined by aluminum (Al):silicon (Si) ratio, of the allophane group. Despite having well-defined crystalline structure in one direction, imogolite will be included in this discussion because it is commonly found in association with allophane.

STRUCTURE

Allophane and imogolite exhibit rolled morphologies with nanometer-scale diameters, and therefore lack the long-range ordered orthogonal lattices observed in macroscopically crystalline materials, although imogolite exhibits long-range order in one direction. Although allophane and imogolite are difficult to characterize due to their small size and lack of macroscopic crystal ordering, research has illuminated much about their structure and formation.

Imogolite

Imogolite exhibits nanotubular morphology. Nanotubes are typically 2 nm in exterior diameter and the strands may be tens of nanometers in length (Fig. 1). These tubes are thought to consist of a rolled gibbsite-like sheet of octahedrally coordinated Al (Fig. 2) with isolated silicon tetroxide tetrahedra bonded to the tube interior to yield an overall Al:Si ratio of 2:1.^[2] Each orthosilicate unit is bonded to three Al atoms and no silica polymerization is observed. As a result of its tubular morphology, imogolite has no long-range structure in the cross-tube direction but does possess long-range structure in the along-tube direction. Computer modeling has confirmed this structure and reproduced the X-ray diffractogram of natural imogolite samples.^[3,4] In synthesis experiments, imogolite has been observed to evolve from nanospherical allophane-like structures upon aging for periods of >2 weeks.^[5]

Allophanes

Owing to their lack of long-range order, allophanes have been difficult to characterize by standard methods such as X-ray diffraction,^[6] and most of the information known about their chemical structures has been determined by methods such as infrared (IR) and nuclear magnetic resonance (NMR) spectroscopy or by computer modeling. The detailed methodologies that are used to study short-range ordered minerals are beyond the scope of this discussion. For information, the reader is directed to the excellent reviews of Dahlgren,^[7] Wada,^[8] and Parfitt.^[6]

Fig. 1 Electron micrograph showing the fine tubular morphology of imogolite. The arrow indicates spherical allophane units. **Source:** Photo courtesy of R. Dahlgren.

Natural allophanes display a continuous variation in Al:Si ratio and a corresponding variation is observed in their structures. High-Al or proto-imogolite allophane exhibits an Al:Si ratio of approximately 2:1. It is thought to have a hollow, nanospherical structure that is similar in cross section to the cross-tube structure of imogolite.

Fig. 2 Modeled allophane porous nanoball (top) and imogolite nanotube (bottom) structures, after Abidin, Matsue, and Henmi.^[1]

In the proposed structure, an exterior gibbsite-like sheet of octahedrally coordinated Al is rolled into a nanoball of diameter 3.5–6 nm (Fig. 2). Orthosilicate units are bonded to the nanoball interior as in imogolite. Computer modeling suggests that four to six pores are present in the nanoball structure.^[1,9] These pores may permit exchange of ions or molecules into or out of the sphere and so are likely to affect the unusual sorption properties of allophanes.

Allophanes with higher Si contents have Al:Si ratios as low as 0.9.^[6] NMR and Fourier transform infrared spectroscopy analyses suggest that high-Si allophanes formed in soil environments have a similar fundamental structure to high-Al allophanes, and that the additional silica is accommodated in a polymerized form in the nanoball interior. The lowest Al:Si ratios are found in “stream-deposit” allophanes that precipitate from silica-saturated stream or spring water. In these highly Si-enriched allophanes, the framework is proposed to be a nanospherical shell of polymerized Si, with a partial or fragmental octahedral Al shell and with some Al substitution in tetrahedral sites.^[10]

OCCURRENCE

Allophane and imogolite are most commonly found in Andisols and tephra-derived Spodosols, although occurrences have been described in other settings.^[6] In general, they precipitate from soil solutions containing Si and Al dissolved from parent material. Laboratory syntheses have produced allophane and imogolite precipitates from millimolar to decimolar solutions of Si and Al. The solution composition affects the composition of the allophane formed with higher silicic acid concentrations leading to lower Al:Si ratios. Alkali and alkaline earth cations in solution have also been found to affect the relative stability of allophane and imogolite by interfering with the dissociation of orthosilicic acid.^[1]

These experimental results illuminate observations of natural systems, summarized by Parfitt.^[6] High-Al and proto-imogolite-type allophanes are characteristics of sil-andic soils, although some soil allophanes display Al:Si ratio close to 1. Si isotopic analyses suggest that allophane precipitates from solution after opaline silica and that its formation is controlled by Al availability, as influenced by Al complexation with organic matter.^[11] Allophane may also form in the absence of tephra, from weathering of aluminosilicate minerals. The presence of organic acids may interfere with allophane formation at lower pH by complexing Al^{3+} ions. This may lead to the formation of alu-andic horizons, which largely lack allophane.

In addition to terrestrial soils, allophane and possibly imogolite have been identified as possible phases on Mars, where they are considered to be likely indicators of tephra weathering under earth-like conditions.^[12]

PROPERTIES

Probably the most well-noted property of allophane minerals is their high water-holding capacity. Imogolite, for example, was shown to have 1.5 times higher water retention than pure sodium (Na)-montmorillonite at -650 J/kg, and water retention of allophane also exceeded that of Na-montmorillonite at above -400 J/kg.^[13] Owing to their porous structures, allophanes have water contents (structural and hydration) ranging from 35.5% to 37.5% by weight.^[14] Allophanic soils, therefore, tend to have relatively high plant-available water contents that are desirable for agricultural and agroforestry production systems. Andisols of the inland Pacific Northwest that support high productivity forests have greater amounts of plant-available water compared to nonandic soils with similar textures (Fig. 3).

Low bulk density is a definitive feature of the Andisol soil order. As Andisols typically have particle densities ranging between 2.5 and 2.7 g/cm³, the relatively low bulk density has been attributed to the development of porous structure.^[15] Bulk density values of allophanic Andisols with relatively low-organic matter content (<3%) decrease with an increase in the allophane content, thereby suggesting that allophane is the main noncrystalline material that results in porous structure.^[16]

It has been noted that Andisols exhibit irreversible changes in water retention, clay dispersibility, and liquid limit upon drying, with the degree of change strongly correlated to oxalate-extractable Al, iron, and Si.^[16] Air-dried allophane, for example, has water contents that range from 23% to 29% of fresh allophane.^[13] The alteration of physical properties after drying has been attributed to

irreversible aggregation.^[13] Allophane, even after treatment to enhance dispersion, tends to form chain-like flocs or domains that alter its physical properties.^[17]

Because of its charge characteristics and high surface area, allophane acts as an important sorbent in soils. Strong sorption of phosphorus (P) on allophane has particularly important implications for nutrient cycling in soils. It has been argued that P sorbs to reactive Al–OH groups in allophane.^[6] However, several studies suggest rather that P sorbs to allophane by displacing weakly bonded orthosilicate groups, damaging the allophane structure.^[18,19] Total P sorption depends on allophane Al:Si ratio, and imogolite sorbs less P than allophanes.

Allophanic soils accumulate relatively large amounts of organic matter when compared with other soils, and interaction between allophanic materials and soil organic matter may be critical in long-term stabilization of carbon in many soils.^[20] Some evidence, however, suggests carbon stabilization by allophane may occur relatively slowly and may be selective for more decomposed carbon compounds.^[6] Allophane has been shown to stabilize organic matter through both direct and indirect mechanisms. Organic matter can be sorbed onto the surface of allophane minerals through ligand exchange reactions. Indirectly, allophanes release Al into soil solution as a result of weathering. Subsequent formation of Al–humus complexes causes the retardation of organic matter decomposition.^[6] The accumulation of organic matter contributes to the water retention capacity of Andisols.

CONCLUSION

Allophane and imogolite are unique and difficult to study, but a combination of analytical, experimental, and modeling work is beginning to elucidate their structures. They lend distinctive properties to soils, most notably high capacities for retention of both soil water and nutrient anions such as phosphate and for long-term stabilization of organic matter. They are primarily found in soils formed on volcanic tephra, and the special characteristics of these minerals and their strong influence on soil properties were recognized with the formation of the Andisol order, which is one of two orders defined primarily by parent material. It is important to carefully consider the properties of these minerals when managing allophanic soils.

Abstract

Alpine soils are found in mountainous regions above the natural subalpine tree line. This high-altitude belt is characterized by a lack of trees and dominance of a continuous grass carpet. The global land area covered by alpine soils is fragmented into many mountain regions (Rocky Mountains, Alps, Himalayas, Atlas, Andes, East Africa Mountains, New Guinea Highlands, New Zealand Alps, etc.) and approaches approximately 4×10^6 km². As a function of time, topographic conditions, and parent materials, a large range of soil types exists. However, alpine belt environment specificity leads to common features for all alpine soils. Because of the last glaciation, alpine soils are young (<10,000 years BP) and strongly influenced by a periglacial environment. On steep slopes, soils are often thin, regularly truncated, and in a constant process of rejuvenation. However, deep soils are found in some alpine grasslands on highly weatherable parent materials. Organic matter accumulation, acidification process, and a great role of aeolian dust deposition are other general characteristics of alpine soils genesis. The alpine soils are fragile and subjected to severe environmental threats, such as overgrazing, acid deposition, and climate change.

THE ALPINE BELT ENVIRONMENT

The altitude of the tree line (i.e., the zone of transition between the continuous forest and the alpine grassland) varies strongly with latitude. Close to the equator, this tree line is found at approximately 3600 m a.s.l., whereas in the regions above 60°, this limit is virtually at sea level (Table 1). This limit also varies in space with slope exposition and in time according to both climatic changes and human activities. The alpine ecosystem is often called “alpine grassland,” “alpine tundra,” or “alpine meadow.” In tropical zones, this belt is often known by local names: “paramos” and “punas” in the Andes and “afroalpine belt” in East Africa. Other than graminoid tussock, alpine vegetation is composed mainly of dwarf shrubs and herbaceous dicotyledonous species, which typically occur in a complex mosaic of communities as a function of topographic position, soil properties, and distribution of snow.^[1]

The alpine soil temperature regime^[2] is generally cryic with an average decrease of 0.6°C for every 100 m of elevation increase. The alpine belt experiences considerable fluctuations in temperature between day and night, with frequent night frost in tropical as well as in temperate zones. In addition to the diurnal cycles, deeper soil freezing and thawing may occur following seasonal cycles in temperate zones.

Rainfall generally increases with altitude. However, in high mountains, condensation occurs well before air masses attain the summit, leading generally to a lower annual rainfall in the alpine belt than in the subalpine forest.

Substantial cloud moisture input is another important characteristic of alpine climate. The snow regime has a great impact on preventing soil and plant exposure to low-temperature extremes. The general pattern of alpine climate may be disrupted by a number of local factors (e.g., the “foehn effect” with opposition between the very wet windward and the very dry leeward).^[1,3]

Erosional (“cirques,” “U-shaped valley”) and depositional (“moraines”) glacial landforms are prominent in the alpine belt. Steep upper slopes, usually consisting of rough rock outcrops, and extensive lower slopes of rock debris are commonly observed (Fig. 1).

FACTORS OF ALPINE SOILS FORMATION

Erosion and Rejuvenation

Steep slopes are subject to strong erosion, especially if stabilizing vegetation is absent. In these slopes where soil losses are higher than the rate of soil formation, alpine soils are regularly truncated and in a constant process of rejuvenation with shallow depth, high skeleton soil content, and low fine earth fraction (Fig. 2).^[3]

Periglacial Phenomena

Among the physical effects on alpine soil formation, the processes caused by freezing play a central role. Permafrost

Table 1 Latitudinal distribution of the areas of alpine life zone and main mountain ranges with alpine environment.

Latitude range (°)	Approximate altitudinal boundaries of alpine life zone (m. a.s.l.)	Area within alpine life zone (km ²)	Main mountain ranges
<60°N	0–500	824,000	Brooks Range, Alaska Range (United States), Kjollen Range (Norway, Sweden), Gory Putorana, Chersky Range, Verkhoyansk Range, and Kolyma Mountains (Russia)
60°N–50°N	1,000–2,500	428,000	Rocky Mountains (Canada), Saigan Mountains, and Yablonovy Range (Russia)
50°–40°N	2,000–3,500	724,000	Cascade Range, Rocky Mountains (United States), Alps (France, Italy, Switzerland, and Austria), Apennines (Italy), Pyrenees (Spain and France), Carpathians (Slovakia, Ukraine and Romania), Caucasus (Armenia, Georgia, Azerbaijan, Turkey, etc.), Altaï (China, Mongolia, Russia, and Kazakhstan), and Tien Shan (China)
40°N–30°N	3,000–4,500	1,088,000	Sierra Nevada, Rocky Mountains (United States), Atlas Mountains (Morocco and Algeria), Zagros Mountains (Turkey, Iraq, and Iran), Hindu Kush, Pamirs, Karakoram, Kunlun Mountains, Plateau of Tibet, Himalayas, Ningling Shan, Dxue Shan, and Bayan Schan (Afghanistan India, China, Pakistan, Kyrgyzstan, and Uzbekistan)
30°N–20°N	3,250–4,750	208,000	Sierras Madre Occidental and Oriental (Mexico), Himalayas, and Plateau of Tibet (India, Nepal, Bhutan, and China)
20°N–0°	3,500–5,000	18,000	Andes (Colombia and Ecuador), Sierra Madre del Sur (Mexico, Guatemala, Salvador, and Honduras) Cordilleras de Talamanca (Costa Rica), Ethiopian Highlands (Ethiopia and Eritrea), and East African Highlands (Kenya)
0°–20°S	3,250–4,500	280,000	Andes (Ecuador, Peru, and Bolivia), East African Highlands (Kenya and Tanzania), and Pegunungan Maoke (Indonesia and New Guinea)
20°S–30°S	2,750–4,000	150,000	Andes (Bolivia, Chile, and Argentina) and Drakensburg (South Africa)
30°S–40°S	2,000–3,000	60,000	Andes (Chile and Argentina)
>40°S	1,000–2,000	220,000	Andes (Chile and Argentina) and New Zealand Alps (New Zealand)

and their related Cryosols^[4] or Gelisols^[2] are found only in the nival belt above the upper limit of higher plant distribution.^[1] In the alpine belt, soils are strongly affected by freeze/thaw cycles with fragmentation of rocks, creeping, solifluction, and cryoturbation phenomena, which disrupt

and dislocate horizons, displace and incorporate materials from other horizons, and mechanically sort soil particles^[1,3] (Fig. 3). In flat terrain, deep frost tables can induce water logging.

AEOLIAN DUST DEPOSITION

Aeolian dust is an important soil-forming factor in alpine soil pedogenesis.^[3] In acidic materials (quartzitic residuum, granite, and gneiss), the steady supply of eolian carbonates through wind-blown materials greatly contributes to raise the pH of surface horizons close to neutrality.^[5,6] The original particle size of the soil may be changed, if the allochthonous particles mix with autochthonous ones.^[3] In volcanic regions (Northern Andes, East African Mountains, New Zealand, etc.), alpine soils are developed from volcanic pyroclastic materials, and volcanic ash can strongly influence alpine soil genesis even in the case of non-volcanic parent materials.^[7]

Weathering and Soil Formation Rate

After the glacier retreat, the greatest change in soil chemistry of alpine soils occurred within the first 3000–4000 years of soil development.^[3] Despite the cold climate, chemical weathering was intense^[3] and soil development proceeded more rapidly in the alpine zone than in the subalpine and mountain forests.^[6] However, it is the degree of parent material fragmentation that largely controls the rate of alpine soil formation.^[3]

In parent rocks containing carbonates, solubility phenomena are especially important. High precipitation and low temperature of the percolating water increase carbonate solubility. Rapid dissolution of CaCO_3 is a common feature of alpine soil weathering.^[3,8]

Soil Organic Matter and Biological Activity

Alpine soils are often characterized by relatively high organic matter content ($>50 \text{ g kg}^{-1}$) in the surface soil with a good incorporation of organic matter through the profile linked with abundant below-ground production of meadow grasses.^[1,9] Both substrate properties with high organic content resistant to mineralization and climate conditions prolong the mean residence time of organic matter.^[1] Faunal and microbial activity of carbon (C) mineralization is clearly reduced under alpine field conditions.^[1,10] Soil biodiversity and activity have been found to vary strongly with characteristic seasonal microclimatic conditions (snow regime, soil moisture, etc.) and spatial distribution of vegetation.^[1]

MAJOR SOILS IN ALPINE BELT AREAS

Using the two international systems of classification,^[2,4] one can find a large variety of alpine soil types over very short distances. However, in the former U.S. soil classification system, the soils of grassy meadows above the timberline were all classified in the “alpine meadow soils” overgroup of the intrazonal order.^[11]

In the steep slopes and in the zone with constant rejuvenation of the profiles, Leptosols (rendzic Leptosols over calcareous materials and umbric Leptosols over acid rocks) and Regosols^[4] are the main soil types found in the alpine belt (Fig. 1). The stability of the slope and the rate of water erosion are the main factors controlling the occurrence of these poorly differentiated soils in the alpine zone.^[3] On stable slopes and over parent materials, highly weatherable and providing weathered materials rich in clay (e.g., some micashist), Cambisols,^[4] or Inceptisols,^[2] and frequently deep soils are found.^[3,9] On stable slopes and over granular crystalline acid rocks, we can sometimes observe the occurrence of podzols in the alpine belt.^[3] However, the podzolization process is often limited by aeolian dust of calcareous materials.^[6,7] Over limestone and parent materials containing both large amounts of phyllosilicates and calcite (calcschale, calcareous micashist, etc.), the rapid and intense decalcification process leads to the formation of a large range of alpine soil from more or less decalcified Cambisols^[3] to locally true podzols.^[8]

The occurrence of poorly drained soils (Gleysols) in alpine environment is common.^[5] Their distribution is a function of topography and they show a morphology that is primarily determined by the effect of frost. They may have peat surfaces. Histosols are also frequent in flat topographic situations (Fig. 4).^[1]

In wet climate conditions, when the aluminum (Al) availability of the parent rock is high, especially on volcanic ash but also in non-volcanic areas, non-allophanic Andisols with high amounts of Al–humus complexes and great accumulation of organic matter have a great extension in the alpine belt.^[7,12]

ALPINE SOIL LAND USE AND MANAGEMENT

Alpine soils play a major role in the functioning and conservation of the unique alpine ecosystem^[1] and in the hydrologic function of mountain belts.^[13] Thus change of alpine soil properties linked with land use change has raised concerns.^[1,13] Traditional, man-made alpine pasture near the tree line has been common in all mountainous regions for at least 7000 years.^[1,13] In parts of Europe, abandonment of these pastures affects soil dynamics.^[1,8] However, in most of the world, alpine soils are submitted to increasing grazing pressure, leading to rapid degradation and erosion.^[13] Other more localized form of alpine land use is the construction of ski runs, which frequently leads to the complete destruction of natural soils. Acid deposition, with the low buffering capacities of thin soil layers in alpine areas, is an other important threat for alpine soils.^[1,13]

ALPINE SOIL AND GLOBAL CLIMATE CHANGE

High mountain ecosystems are generally considered to be particularly sensitive to climate warming. Therefore they appear to be useful “ecological indicators,” and extensive work has been done to study climate changes in alpine ecosystems.^[1,13,14] Overall warming and associated change in precipitation patterns and snow cover will drastically influence alpine vegetation with change in diversity and abundance of certain species. The possible impact of projected climate change on alpine soils is then firstly linked with the alpine vegetation change.^[13,14] As in other regions but possibly with higher intensity, the climate change will influence both C balance (C mineralization vs. C sequestration) and mineral balance (weathering vs. erosion) in alpine soils with apparent contradictory

effects. The increase in temperature could substantially increase the depth of soil’s active layer, leading to: 1) higher rates of soil organic C decomposition but with a longer growth season and 2) increase of C inflow (increase of the C pool in alpine soils). In the same way, the consequences of climate change on the mean soil depth are unclear. With higher temperature, an increase of the weathering rate is anticipated. However, evidences are accumulating that as heavy rainfall events (associated with global warming) become more frequent, erosion of alpine soils is likely to be enhanced.^[1,13,14]

Abstract

Aluminum (Al), a light metal, is ubiquitous in soils. At low pH, toxic Al species can form that inhibit plant root growth and thereby limit ecosystem productivity. The occurrence of toxic Al species in soils and the effect of these forms on plant physiology and root growth are reviewed. Agricultural management practices aimed at limiting Al toxicity and plant-based Al resistance mechanisms are also discussed.

INTRODUCTION

Aluminum (Al) is the most common metallic element in the earth's crust (8%) and the third most common element after oxygen and silicon on the earth. The dissolution of the minerals, namely gibbsite and boehmite,^[1] releases Al and ultimately controls the concentration of Al in solution in many soils,^[2–5] although factors, such as dissolved organic matter, also influence the total Al concentration present. Al plays an important role in the environment as many soils (Spodosols, Alfisols, Inceptisols, and Histosols in cold and temperate climates and Oxisols and Ultisols in tropical climates) are acidic either naturally (due to high rainfall leaching of base cations) or due to anthropogenic (use of ammonium fertilizers, legumes in cropping systems, acid rain) influences.^[6] It is estimated that approximately 30% of the world ice-free land area is occupied by acid soils of which approximately 180 million hectares are used for agricultural production.^[6] In solution, Al is highly toxic to plants, *Rhizobium* bacteria in soils, aquatic organisms in fresh waters,^[7] and to a lesser extent soil fauna. Al has been implicated among others in Alzheimer's disease and dialysis dementia in humans.^[8,9]

OCCURRENCE AND USES

Al is a stable element with 100% abundance as the ²⁷Al isotope. The pure metal, which is non-magnetic, does not occur in nature and Al is only found as a constituent in minerals such as mica, feldspar, and some gemstones. Al-containing minerals weather initially to 2:1 layer aluminosilicate clay minerals (e.g., vermiculite, montmorillonite), which upon further weathering form 1:1 layer aluminosilicates such as kaolinite. Further weathering of clay minerals

leads to leaching of silica and base cations leaving behind hydrous aluminum oxide (e.g., gibbsite) in the form of bauxite, which is an important Al ore. Bauxite is digested with hot alkali (Bayer process), yielding insoluble impurities (red mud) and aluminate, which is precipitated as Al(OH)₃ and electrolyzed in molten cryolite to yield metallic Al. The metal has a low specific gravity (2.7 g cm⁻³) and is resistant to corrosion due to formation of an oxide film on the surface. Consequently, the metal is extensively used in the building and construction industries; automotive, shipping, and aerospace industries; manufacture of power lines; and for food packaging. Al salts and compounds are used for water purification, as catalysts in the chemical industry and as ingredients in cosmetics.

CHEMISTRY OF AL

Al is an amphoteric element, dissolving both at low and high pH with minimal solubility around pH 6–7.^[10] Soluble Al³⁺, which is not redox reactive, is classified as a “hard” acid due to its very small ionic radius of 0.53 Å and reacts strongly with “hard” ligands such as oxygen and fluoride.^[10,11] It also forms stable complexes with di- and multidentate ligands (chelate effect).^[10] The dissolution of Al minerals at low pH releases octahedral Al³⁺, which is hexacoordinated with water molecules.^[11] Octahedral Al³⁺ gives a broad peak on ²⁷Al nuclear magnetic resonance (NMR) spectra.^[12,13] As the pH of an acidic Al solution is increased to 4, hydrolysis of Al occurs, giving rise to a series of Al hydroxy species (AlOH²⁺, AlOH₂⁺, and Al(OH)₃),^[11] which may undergo aggregation (polymerization) via OH bridges if the Al concentration is sufficiently high (>10 μM).^[14] As the pH is raised above 6, Al changes its coordination number to 4 and yields tetrahedral

aluminate (AlOH_4^-),^[11] with a sharp and well-defined peak at ~63 ppm upfield of Al^{3+} on ^{27}Al NMR spectra.^[12,13]

POLYMERIZATION OF Al

Depending on the pH and Al concentration in solution, hydrolyzed Al species may aggregate and form polymeric (polycationic) Al species such $\text{Al}_2(\text{OH})_2^{4+}$, $\text{Al}_3(\text{OH})_4^{5+}$, $\text{Al}_8(\text{OH})_{20}(\text{H}_2\text{O})_x^{4+}$, the “gibbsite fragment” model forms, $\text{Al}_6(\text{OH})_{12}(\text{H}_2\text{O})_{12}^{6+}$ through $\text{Al}_{54}(\text{OH})_{144}(\text{H}_2\text{O})_{36}^{18+}$, $\text{Al}_{13}\text{O}_4(\text{OH})_{24}(\text{H}_2\text{O})_{12}^{7+}$ (Al_{13}), and $\text{Al}_2\text{O}_8\text{Al}_{28}(\text{OH})_{56}(\text{H}_2\text{O})_{26}^{18+}$ species.^[12,15–17] While many more Al polymers have been proposed, the experimental evidence in support of these species is limited. The lack of suitable analytical approaches for the determination of polymeric Al species may mean that other species form but cannot be detected with sufficient accuracy.^[12] The polymeric Al species are metastable with a half-life for Al_{13} of several hundred hours,^[18] which imply that the species undergo depolymerization or crystallization with time. It is generally accepted that sulfate, phosphate, fluoride, silicate, and organic acids prevent or reverse Al_{13} formation,^[12,19–21] and crystalline gibbsite may induce crystallization and depolymerization of Al_{13} .^[22] As sulfate and silicate ions are prevalent even in acid soils, the natural occurrence of Al_{13} in soil solution is considered unlikely.^[12,23] However, there is evidence that Al_{13} may form in the cell wall of plant roots^[24–26] even if the conditions in bulk solution are not favorable for Al_{13} formation. Clearly, this area requires further research.

TOXICITY OF Al

Toxicity of Al to plants is mainly manifested by an inhibition of root growth and while it is considered that Al^{3+} and Al_{13} are the most toxic species,^[27,28] studies correlating Al species and their activity with degree of root growth inhibition have given poor results. This is due to the several Al-hydroxy species that coexist within a narrow pH band and cannot be investigated in isolation. Furthermore, the activities of individual species must be calculated from equilibrium data that may be uncertain.^[29] The critical Al concentration at which root elongation is inhibited is as low as 5–20 μM in solutions of low ionic strength representative of acid soils. Exact critical values depend on the plant species and the conditions in which the plants are grown. Generally, root hairs are more sensitive to Al toxicity than roots.^[30]

The forms of Al potentially present in solutions extracted from acid soils are listed in Table 1. These forms differ markedly in their effects on plant growth, from having no effect (microcrystals and amorphous precipitates) to being toxic at a concentration <10 μM (Al_{13} and Al^{3+}). It is, therefore, essential that methods be used to discriminate among the various forms that may be extracted.

Table 1 Forms of Al potentially present in solution extracted from soils.

Form	Examples	Phytotoxicity
Microcrystalline	Kaolinite, Gibbsite	Low
Aluminate	AlOH_4^-	
Amorphous precipitates	Al_2SiO_5 , $\text{Al}(\text{OH})_3$, AlPO_4	
Organic complexes		
Low relative molecular mass	Al-citrate, Al-oxalate	FX
High relative molecular mass	Al-fulvate, Al-humate	
Inorganic complexes	AlF^{2+} , AlF_2^+ , AlSO_4^+	
Inorganic monomers	Al^{3+} , AlOH^{2+} , $\text{Al}(\text{OH})_2^+$	
Small polycations	$\text{Al}_2(\text{OH})_2^{4+}$, $\text{Al}_3(\text{OH})_4^{5+}$	
Large polycations	$\text{AlO}_4\text{Al}_{12}(\text{OH})_{24}(\text{H}_2\text{O})_{24}^{7+}$	High

PHYSIOLOGICAL BASIS OF Al TOXICITY IN PLANTS

Root growth is more inhibited than shoot growth by Al. Consequently, yield may be drastically reduced by Al in acid soils without developing clear and diagnostic foliar symptoms. Root growth inhibition results in short stubby roots and absence of root hairs. The main site affected by Al is the elongation zone of roots (1–4 mm behind the root tip).^[32,33]

The inhibition of root growth by Al is a very rapid process, occurring within 30 minutes of exposure to Al.^[33] This points to involvement of the apoplast (i.e., the cell wall and the exterior side of the plasma membrane) in fast Al responses.^[34] Owing to the proximity of the cell wall and plasma membrane in addition to physical interaction between the two (e.g., by cell wall associated kinases^[35–37]), it is beyond contemporary experimental approaches to distinguish between cell wall and plasma membrane effects *in vivo*, while *in vitro* approaches are plagued by artifacts.

Binding of Al to negative charges of the cell wall (contained on hemicelluloses, pectin, and proteins) interferes with processes necessary for cell expansion and thus root elongation.^[38,39] For instance, binding of Al to pectin renders pectin resistant to degradation by enzymes,^[40] in turn reducing mobility of enzymes necessary to cleave load bearing hemicellulose molecules,^[41,42] resulting in stiffening of the cell wall.^[38,43] The desorption of bound Al with organic acids, which chelate Al,^[44] leads to a recovery in cell and root elongation.^[39] While extensions, a group of proteins responsible for cell wall loosening, are inhibited by 1 mM Al *in vitro*,^[41,45] it is uncertain if inhibition also occurs at Al concentrations known to inhibit root growth

(namely 5–20 μM). Furthermore, binding of Al to the cell wall reduces the negative charge (CEC) of the cell wall and affects accumulation of ions in the cell wall. This can lead to a decreased state of hydration of the cell wall^[46] and decreased transmembrane potential.^[47] Interactions of Al with sodium (Ca), potassium, and anion channels in the plasma membrane have been described^[48–50] with implications for the transmembrane potential.^[51] Rapid transient changes in the cytosolic (intracellular) Ca concentration have been observed, which can interfere with the cytoskeleton^[48,52] and induce callose formation.^[52] Al also affects the fluidity of the plasma membrane^[53–55] and may trigger the generation of reactive oxygen species,^[56–58] which in turn can crosslink cell wall polymers.^[59] Cytosolic Al effects have been postulated for the Ca homeostasis, oxidative stress responses, cell division, and energetic processes.^[51] However, these processes are affected sometimes after the initial inhibition of root elongation, suggesting that the primary site of Al toxicity is in the cell wall. For reviews dealing with Al toxicity, the reader is referred by Rengel and Zhang,^[52] Barceló and Poschenrieder,^[60] Horst,^[61] Kochian et al.,^[62] and Zheng and Yang.^[63]

RESISTANCE AND TOLERANCE MECHANISMS IN PLANTS

The ability of a plant to withstand high Al concentrations in soil can be mediated by either resistance mechanisms (i.e., exclusion of Al from the apoplast and cytoplasm) or by tolerance mechanisms (i.e., accumulation of Al in the apoplast and symplast). Considering the economic importance of Al toxicity, a great deal of research has been conducted into Al resistance and tolerance mechanisms, and there are detailed reviews of this topic available.^[60,64–69] Several plant species naturally occurring on acid soils are tolerant toward Al and even accumulate Al in leaves and plant tops [e.g., tea (*Camellia sinensis*) and some eucalypts and rain-forest plants]^[67,68,70–74] in the form of organic or inorganic Al complexes or bound to the cell wall. Al resistance can be imparted by organic acid exudation from plant roots and it has been demonstrated that genetic engineering for increased organic acid synthesis and exudation conferred Al resistance to previously sensitive species.^[75,76] Complexation of Al by peptides^[77] and exuded organic acids, in particular malic, citric, and oxalic acid, has been found for a number of Al resistant species; however, the importance of this strategy is debated.^[78–81]

A further resistance mechanism has been suggested in the modification of the rhizosphere pH by plant roots.^[82,83] An alkalization of the area immediately surrounding the zone of root elongation may hydrolyze or precipitate Al and thereby prevent formation of rhizotoxic Al species.^[84,85] Finally, there is evidence suggesting that the affinity of plant root cell walls for Al may be different between Al-sensitive and resistant plants.^[25,46,86,87]

AMELIORATION OF Al TOXICITY

Generally, applying dolomite or calcite limestone is the most effective way of dealing with Al toxicity since it raises the soil pH (through precipitation of $\text{Al}(\text{OH})_3$) and supplies Ca and magnesium ions, which compete with Al for binding by roots and soil particles. The application of single superphosphate has a similar effect through the precipitation of Al phosphate and formation of less toxic AlSO_4 . Agronomically, use of Al tolerant crop plants in conjunction with liming is the most effective way of dealing with acid soils. Organic matter addition may complex soluble Al and alleviate Al toxicity,^[88] although large quantities may be required depending on their ash alkalinity.^[89]

Amazon Basin Soils

Stanley W. Buol

*Department of Soil Science, North Carolina State University, Raleigh,
North Carolina, U.S.A.*

Abstract

The Amazon basin is approximately 7×10^6 km² in area. The watershed encompasses parts of Brazil, Venezuela, Colombia, Ecuador, Peru, and Bolivia. About 80% of the area is vegetated with tropical rain forest. The paucity of roads and sparse human habitation continue to inhibit extensive investigations, although limited studies have clearly established that significant differences in soil composition are present within the basin. The extent and geographical distribution of soil properties is only partially known as vast areas of the basin hide their soil properties under dense vegetative canopies that have fostered popular generalizations about the infertile composition of all the soils because of the severity of leaching in the humid tropical environment. It is known that significant areas of relatively fertile soils, related to the composition of the initial parent materials, are present throughout the basin.

SOIL TEMPERATURE AND MOISTURE REGIMES

Lying within tropical latitudes, soils in the basin share one common characteristic of nearly uniform temperature throughout the year, i.e., isothermic (15–22°C mean annual soil temperature) soil temperature regimes (STRs) at higher elevations and isohyperthermic (mean annual soil temperatures greater than 22°C) STRs at lower elevations. Perudic soil moisture regimes (SMRs) are present where rainfall exceeds potential evaporation every month of the year on the lower slopes of the Andean mountains in the western portion of the basin. Udic SMRs are present in much of the western and eastern portions of the basin where the soil moisture is available for plant growth almost every month each year. Ustic SMRs are present in the central and southern portions of the basin where a lack of rainfall limits plant growth for 3–6 months each year.^[1] Soils that are saturated in a portion of each year, aquic soil moisture conditions, are prevalent along flood plains and in other broad-level areas throughout the basin.

UPLAND SOILS (TERRA FIRME)

Soil texture, mineralogy, and chemical composition contrast in response to the composition of sedimentary material that filled the basin. Much of the basin consists of fluvial and lacustrine sedimentary materials of contrasting texture (Fig. 1). As these sediments are dissected by meandering river valleys, broad, flat terrace-like upland plateaus are formed and vegetated by upland species that hide significant soil textural contrasts (Fig. 2).

A major contrast in composition of sediments is present in the basin. The Guiana and Brazilian shields contributed

infertile sediment almost devoid of weatherable minerals from Precambrian rock to the eastern portion of the basin. During the Tertiary period, the uplift of the Andean mountains reversed the flow of water within the basin, and erosion from the Andes contributes less weathered materials, often lime-rich and weathered volcanic materials to the western portions of the basin and modern flood plains.^[2] The Andean sediments are present west of the Rio Negro and Madeira rivers in Brazil^[3] and extend into Peru,^[5,6] Columbia, Ecuador, and Bolivia. The sediments derived from the Andes contain more weatherable minerals and are more nutrient-rich than those to the east that are derived from the Guyana and Brazilian shields. Ultisols^[4] [*Podzólicos Vermelho-Amarelo Distrófico*; throughout this entry, soil names from *Soil Taxonomy*^[4] are followed by the *Brazilian soil classification*^[3]] predominate in the upper basin, while Oxisols (*Latossolos*) predominate in the lower portion of the basin. Although Ultisols and most Oxisols are nutrient-poor, significant inclusions of more nutrient-rich material are present within the basin. Although long undetected in the poorly explored and sparsely inhabited basin, large areas of Alfisols (*Podzólicos Vermelho-Amarelo Eutrófico*) are formed in base-rich sediments in western Brazil primarily in the states of Rondonia and Acre and surrounding countries. The presence of these base-rich soils belies the extensive leaching often cited as the cause of low fertility and acidity of soils in the basin. Mollisols and high base status Inceptisols, some with free calcium carbonate present within a few centimeters of the surface, have been observed in upland areas with more than 5 m of annual precipitation. The Brazilian soil classification system recognizes Eutrófico as having high base saturation percentage and Distrófico as having low base saturation percentage, at the phase level of both *Latossolos* and

Fig. 1 Aerial view of meander scars along Rio Marañon, a major tributary of the Amazon River in Peru. The tree-vegetated levees are sandy while the inundated areas are of clayey texture.

Podzólicos.^[3] Cursory translations of Brazilian literature that equate Latossolos as Oxisols and Podzólicos as Ultisols often concealed the significance of base saturation percentage. Canopies of dense tropical forest vegetation blanket almost all upland areas in the basin, and base saturation percentage is not visually evident from aerial observations. Significant areas of the more chemically fertile soils are discovered only when more detailed soil surveys, supported by laboratory data, are conducted. Subsistent farmers become aware of the more base-rich areas only after a few years of crop production. The more base-rich soils tend to remain in crop production and cattle grazing, while adjacent low base saturated soils are abandoned to forest regrowth.

East of the confluence of the Rio Negro and Rio Madeira near the city of Manaus, the predominant upland soils near the main channel of the Amazon River and also further south in the state of Mato Grosso are xanthic Oxisols (*Latossolos Amarelo, Distrófico*). These soils have a distinctive reddish-yellow to yellow color and have been found to contain less

Fig. 2 Aerial view of a river and oxbow lake formed as a tributary of the Amazon River entrenches within the Amazon basin in Peru.

iron oxide and fix less phosphate fertilizer than more reddish Oxisols.^[7,8] Extensive areas of Ultisols (*Podzólicos Vermelho-Amarelo Distrófico*) are also present in association with the Oxisols on uplands both north and south of the Amazon River. The Oxisols appear to be formed in transported and preweathered sediments, while the Ultisols are formed from residual rock and sediments that have slightly higher weatherable mineral content. Where the mineral composition of the rock is mafic (diorite), Alfisols (*Podzólicos Vermelho-Amarelo Eutrófico*) are present. A rather extensive area of the high base status soils is readily seen in association with shallow soils (*Solos Litólicos Distróficos e Eutróficos*) in the south central area of Para State.^[3] Often, these Alfisols (*Podzólicos Vermelho-Amarelo Eutrófico*) are a darker red and have been observed to occupy small areas associated with Ultisols (*Podzólicos Vermelho-Amarelo Distrófico*), illustrating that soils formed in parent rock of basic composition retain a high base saturation percentage under humid tropical leaching.

Some of the upland soils in the basin are formed in very sandy sediments. Soils formed in the sandy sediments are very infertile Quartzipsamments (*Solo Arenoquartzosos Profundos*) where the water table is deep, while Spodosols (*Podzols*) form on sandy sediments where the water table is near the soil surface. It has been estimated that perhaps 10% of the Amazon basin has these kinds of soils.^[9] One major area of sandy soils is in the headwaters of the Rio Negro in the north central part of the basin where it merges with the Orinoco watershed. Smaller areas of sandy soils are scattered throughout the basin, often detectable by the organic stained black, “coffee colored” waters of the rivers that drain these sandy watersheds (Fig. 3).

FLOOD PLAINS

The flood plains along the numerous rivers in the Amazon basin are composed of recent sediments. Many of the

Fig. 3 “Black” water from the Rio Negro as it enters the “white” water of the Amazon River near Manaus, Brazil.

sediments are quite fertile, and montmorillonite clay content is high especially in those sediments derived from base-rich materials. Other areas are infertile where the sediments are derived from siliceous materials. Most of these soils in the flood plains are aquents and aquepts (*Solos Gley*, *Distróficos*, and *Eutróficos*). The base saturation percentage of these soils ranges from high to low depending on the composition of the material in the source area of the individual river. Most flood plains are often quite broad and subject to flooding and stream-bank erosion from seasonal rise and fall of water level in the major rivers. Rivers provide routes for travel, and most human settlements are located on flood-free uplands near the rivers. The presence of anthropogenic soils (*Terra Preta do Índio*) formed from the accumulation of charcoal and other human wastes reveal that agrarian settlements may have existed in the basin for several centuries.^[10]

Road maintenance is extremely difficult in the interior of the Amazon basin where these broad flood plains are seasonally flooded. A seldom-mentioned constraint to road building is the lack of coarse aggregate in the sediments in the interior of the basin. Also, extreme difficulty is experienced when attempting to construct and maintain roads on saturated clayey sediments of high shrink and swell montmorillonite clays.

CONCLUSION

Much of the Amazon basin is poorly explored because of sparse population and lack of infrastructure. The nearly unbroken cover of tropical forest vegetation and the pedogenic dogma of extensive leaching in humid tropical environments have entrapped scientists in the assumption that a uniformity of infertile soil capable only of supporting shifting cultivation is present. This paradigm is changing as transportation infrastructure to support the market needs of continuous agriculture and cattle ranching have facilitated detailed soil studies that

reveal significant contrasts in soil properties not readily apparent from remote aerial observations hampered by dense jungle vegetation.

Amendments and Ameliorants

David C. McKenzie

Precision Land Management, Orange, New South Wales, Australia

Abstract

Soil amendments/ameliorants can be used to overcome many physical problems in soil. For improving soil structural stability, the best-known ameliorants are gypsum (calcium sulfate) and, to a lesser extent, finely ground limestone (calcium carbonate). Other useful inputs include natural and synthetic organic materials.

SOIL STRUCTURE LIMITATIONS

Key Processes

Good soil structure is vital for the growth of most plants (paddy rice is an exception), particularly where water application is either uncontrolled (rainfed) or not easily controlled (flood irrigated). Soil with excellent structural form accepts water readily, drains excess water quickly, and has a broad range of water contents over which waterlogging (poor aeration) and excessive hardness do not limit seedling emergence or root growth.^[1]

Structural form refers to the arrangement of the solid components of soil and the associated pore space.^[2] Structural stability is the ability of soil to retain its structural form when subjected to disruptive forces such as immersion in water.

There are two aspects of soil stability in water: slaking and dispersion.^[3] Slaking refers to the collapse of air-dry soil aggregates into subunits (diameter of about 0.2 mm) when placed in rainwater. It indicates that the bonds created by materials such as organic matter are not strong enough to withstand the forces associated with rapid wetting. If the subunits created by slaking break down further, leading to a separation of clay, sand, and silt, dispersion is said to have occurred. An associated limitation is excessive subsoil swelling. Formation of a dispersed surface seal under wet conditions leads to poor aeration and inadequate water penetration, and the runoff water may then cause erosion. Hard crusts develop when dispersed soil is dried, particularly where the shrink/swell potential is poor.^[2]

As the amount of sodium adsorbed on the surfaces of clay particles increases, so does dispersion. This problem is aggravated by a lack of electrolyte in soil solution. Clay type also is important. Illite disperses more readily than smectite clay, and kaolinite clay become more dispersive as pH increases. The presence of exchangeable magnesium on clay surfaces aggravates

soil dispersion. Several direct measures of soil dispersibility are available.^[4,5]

Management Options

Poor structure can be overcome indirectly by special management inputs. Options include:

1. Raised beds and/or extra nitrogen fertilizer to deal with waterlogging limitations; and
2. The use of drip irrigation systems to apply water in a way that maintains a very narrow range of soil water contents, where neither waterlogging nor soil strength will limit growth.

However, it is usually less expensive and less risky to improve structural stability by adding ameliorants to the soil. The benefits of gypsum application to sodic (dispersive) soil have been recognized since the early 1900s in the United States.^[6] The practice of applying lime (chalk) to improve the structure of clay soil has been carried out for thousands of years in England.^[7] In developing countries, ash and organic household waste often are used to fertilize nutrient-depleted soil^[8] but may also improve soil structure.

Factors to consider before selecting an amelioration strategy include:

1. Soil condition should be measured so that amelioration is based on objective data about the severity of soil degradation.
2. The types and amounts of soil ameliorants that are applied will be strongly influenced by their cost in relation to the requirements and value of the plants being grown.

Secondary benefits, such as overcoming sulfur deficiency with gypsum and reducing acidity limitations with lime, should be considered when choosing an ameliorant. If the

soil has been compacted by heavy machinery, deep ripping may also be required.

AMELIORANTS FOR IMPROVING SOIL STRUCTURE

Gypsum

Gypsum is the main compound used for the reclamation of soil that is dispersive and/or prone to excessive swelling. The benefits of using gypsum to improve soil structural stability are due to both electrolyte concentration and cation exchange effects (replacement of sodium ions attached to the clay surfaces with calcium ions).^[9] Gypsum is available as a mined product or can be obtained as a by-product of industrial processes. Mined gypsum, which has a coarser particle size than by-product gypsum, tends to be less soluble. This is beneficial in situations where a slow-release source of electrolyte and calcium is required. Gypsum can be either spread as a solid or dissolved in irrigation water. A typical application rate on sodic clay soil is 2.5 t/ha for dryland wheat and 7.5 t/ha for higher value irrigated crops.

Soil that is most likely to show an economically viable response to gypsum application has a high clay content (greater than 30%) and is sodic with an exchangeable sodium percentage (ESP) greater than 5.^[11] If the salt concentration in soil is very low, the critical ESP for dispersion may be as low as 2 (as found in the surface of some hard-setting soil types).

Overcoming a soil structure problem with gypsum may introduce new problems. For example, the correction of drainage limitations in a sodic clay soil may lead to a leaching of nitrates and other contaminants beyond the root zone. Therefore, soil water management needs to be adjusted after soil structural stability has been improved. Possible impurities in gypsum products also need to be considered. Mined gypsum often contains traces of clay, while some industrial gypsum may be contaminated by toxins such as cadmium and fluoride compounds. It is important to obtain data about the quality of ameliorants prior to application.

Lime

When the soil pH (measured in water) is less than approximately 7, the application of ground limestone is likely to release substantial amounts of electrolyte and calcium. Lime often is introduced to the soil naturally via irrigation water. Even in soil with an average pH > 7, there may be pockets of soil adjacent to roots with a much lower pH that will encourage the dissolution of lime. Liming products (ground limestone, calcium oxide, and calcium hydroxide) are a more concentrated form of calcium than gypsum. The addition of acidifying

materials^[12] can release calcium by dissolving lime that occurs naturally in soil.

Another option is to apply a blend of gypsum and ground limestone.^[11] The gypsum provides an immediate source of calcium and electrolyte, while the less-soluble lime provides a longer term supply.

Organic Matter

For soil that is prone to slaking, the application of organic matter is likely to be beneficial.^[3] Organic ameliorants are particularly useful for non-swelling topsoil that is prone to hardsetting. Natural organic products include crop residues, animal and poultry manure, and sewage sludge (biosolids). Synthetic soil conditioners such as polyacrylamide are also effective, but cost and poor persistence of benefits limits their use. Organic matter application can reduce dispersion if accompanied by calcium ions.^[13] Organic mulches protect the soil surface from the disruptive effects of raindrop impact. They also encourage soil fauna such as earthworms, which improve soil structure with their burrows and exudates.

CHALLENGES

Modelling the Effects of Ameliorants on Soil Condition and Plant Growth

Numerous field trials have been conducted throughout the world to determine the most effective rates and forms of gypsum (and related materials) for soil that is structurally unstable. However, the results generally are location-specific^[4] and are strongly influenced by climatic conditions. A model is needed to predict the most profitable rates of gypsum and other ameliorants for various land use systems on soil that is prone to slaking and/or dispersion.

Integration of Soil Amelioration Strategies with “Precision Agriculture” Technology

The introduction of crop yield and quality mapping^[14] will help land managers to identify soil structure problems within subsections of management units. This should allow ameliorants to be applied more efficiently via variable-rate application equipment, rather than as blanket applications using conventional machinery. Research is needed to optimize soil sampling strategies for yield map interpretation and to determine the extent to which within-field variability of soil properties can be minimized economically. More attention should also be given to the development of rapid and inexpensive field measurement techniques that allow the ameliorant requirements of soil to be mapped more accurately.

Ammonia: Volatilization from Agricultural Soils

Paul G. Saffigna

Tropical Forestry, University of Queensland, Gatton, Queensland, Australia

John R. Freney

Plant Industry, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Canberra, Australian Capital Territory, Australia

Abstract

Ammonia can be in the form of native organic matter, which decomposes to release ammonia, or fertilizer such as anhydrous ammonia, ammonium salts, or urea. Urea, either from animal urine or fertilizer, is rapidly hydrolyzed to ammonium carbonate in soil. This urease catalyzed reaction results in localized areas of high pH. Apart from the application of anhydrous ammonia, these sources tend to add ammonium ions rather than ammonia to the soil. Therefore, the conversion of ammonium ions to ammonia controls the loss of ammonia.

INTRODUCTION

The exchange of ammonia between soils, plants, waters, and the atmosphere is an important part of the terrestrial nitrogen cycle. The process by which ammonia is lost from the earth's surface to the atmosphere is termed volatilization. The primary source of ammonia for loss is the natural microbial decomposition of amino acids and proteins in dead plants, animals, and microorganisms in soils and waters, but substantial amounts come from the excreta of animals and the use of nitrogen fertilizers.^[1,2] Ammonia (NH₃) has a strong affinity for water and it readily dissolves in it to form ammonium (NH₄⁺) hydroxide:

The ammonia and ammonium ions are in equilibrium and the reaction may be displaced to the left or right depending on the conditions. For example, if the pH of the system is increased by addition of alkali (hydroxyl ions), the reaction is displaced to the left and ammonia gas is formed and lost to the atmosphere. As ammonia is a gas at normal temperatures and pressures, and as the concentration in the atmosphere is usually low, it can be readily lost to the atmosphere. However, volatilization is a complex process affected by a combination of biological, chemical, and physical factors, and the loss process may be hindered.^[1,2]

THE MECHANISM OF AMMONIA VOLATILIZATION

Before volatilization can occur there must be a source of ammonia. This can be in the form of native organic matter,

which decomposes to release ammonia, or fertilizer such as anhydrous ammonia, ammonium salts, or urea. Urea, either from animal urine or fertilizer, is rapidly hydrolyzed to ammonium carbonate in soil. This urease catalyzed reaction results in localized areas of high pH. Apart from the application of anhydrous ammonia, these sources tend to add ammonium ions rather than ammonia to the soil. Therefore, the conversion of ammonium ions to ammonia controls the loss of ammonia.^[1,2]

The relative concentrations of ammonium and ammonia in solution are strongly affected by pH (acidity or alkalinity) and temperature. For example, the percentage of ammonia present at pH 6, 7, 8, and 9 is approximately 0.1, 1, 10, and 50.^[3] Thus the higher the pH, the greater is the potential for ammonia loss from soil. The loss of ammonia from an application of ammonium sulfate increased from nil at pH 7 to 87% at pH 10.5.

The main driving force for ammonia volatilization is the difference in concentration between ammonia gas in the soil and ammonia in the atmosphere. Increasing windspeed increases the rate of volatilization by promoting more rapid transport of ammonia away from the soil surface. A four-fold increase in wind speed resulted in a ten-fold increase in ammonia loss. Ammonia volatilization and water loss from soils are directly related; no ammonia is emitted until evaporation commences.

Any factor which affects the ammonium ion concentration in soil will also affect the ammonia gas concentration and the loss process. Consequently, plant uptake, immobilization by microorganisms, nitrification, and leaching will reduce the amount of nitrogen available for volatilization, whereas increasing the rate of application of ammonium or ammonium producing fertilizers or organic residue will increase the potential for volatilization.^[1,2]

Other factors which control ammonia volatilization are cation exchange capacity, buffer capacity, presence of calcium carbonate, water content of soil, soil texture, plant residues, fertilizer form, radiation, and atmospheric ammonia concentration.^[3] A number of models incorporating these factors have been developed to describe the volatilization of ammonia.^[4]

MEASUREMENT

A number of workers have used canopies over field crops and pastures, combined with acid traps, to measure ammonia loss, but the canopies affect the temperature, moisture, and wind speed in the immediate environment of the plant, and thus the result obtained may not reflect ammonia loss from the natural environment. Simplified micrometeorological techniques have been developed to measure ammonia volatilization in the unconfined field situation, thus allowing the assessment of the importance of ammonia loss, and the factors controlling loss in different agricultural systems with minimum labor, equipment, and skills.^[1,4]

AMMONIA EMISSIONS

Animals and Their Wastes

Waste from farm animals is the principal source of atmospheric ammonia. Ammonia concentrations in the air range from as low as $1 \mu\text{g Nm}^{-3}$ over oceans to 5 in rural areas, 15 in urban areas, 50 in areas of intense animal husbandry, and 1000 over a field shortly after spreading animal waste as a slurry. The importance of animals as a source of ammonia is well illustrated by the situation in Europe, where nearly three quarters of the total emissions are from animals and their wastes (stables 34%, surface spreading 32%, and grazing 8%), and only one quarter comes from a combination of fertilizer application (12%), industry (0.5%), crops (5%), and miscellaneous (8%, e.g., treatment of waste water and sludge, pets, humans, and refrigeration).^[1]

The large loss of ammonia from livestock systems is due to the low conversion of dietary nitrogen into animal protein. More than 75% of the nitrogen intake is excreted in forms that give rise to ammonia emissions. Nitrogen is excreted mostly in urine with some present in droppings as microbial cell constituents and undigested food. Urine contains 70–90% urea which is rapidly hydrolyzed to ammonia by naturally occurring urease. The amount excreted depends on the feed composition—the better the quality of the food the less nitrogen excreted. Factors influencing ammonia emissions include manure properties, weather, soil attributes, and application measures (incorporation, dilution, and soil preparation). Where animals are grazing pastures, about 10% of the excreted nitrogen is lost as ammonia—mostly from urine.^[1]

Cropping Systems

There has been a widespread move to urea as the major form of nitrogen fertilizer used in cropping systems because of its relatively low manufacturing cost and low transportation cost per unit of nitrogen. However, large losses of ammonia have been detected from rainfed and irrigated crops and flooded rice in many countries following applications of urea (Table 1). Ammonia loss from cropping systems is affected by many of the factors discussed above, fertilizer composition, rate, time, and method of application, and factors unique to the crop.

In flooded rice, up to 56% of the applied nitrogen is lost from the system by ammonia volatilization as a result of the growth of photosynthetic algae, which markedly increases the pH of the floodwater during daytime. The new practice of retaining tops and leaves of cut sugarcane plants on the soil surface following green cane harvesting has created problems for farmers when they apply urea. So as not to disturb the residue cover, which has many advantages, including weed control, many farmers apply urea by broadcasting onto the surface of the residue. The sugarcane residue has high urease activity and low ammonia retention capacity, so when the residue layer is moistened by dewfall, rainfall, or condensation of evaporated soil water, some of the urea dissolves, is hydrolyzed, and when the water evaporates, between 30% and 40% of the applied nitrogen is lost as ammonia. Bananas have a very high requirement for nitrogen, frequent applications are made and more than $500 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ is applied. Direct measurements of ammonia volatilization from a banana crop in tropical Australia showed that, when urea was applied onto wet soil, 20% of the applied N was lost even though 90 mm of rain fell during the study. The extensive canopy of banana plants restricted rainwater from falling on the fertilized area and washing the urea into the soil.

Plants can absorb ammonia from the air or release it to the atmosphere. It has been established that plants have an

Table 1 Ammonia volatilized (% of N applied) from different cropping systems fertilized with urea.

Plant	Treatment	Loss
Bananas	Surface applied	20
Corn	Surface applied	22
Rice	Broadcast into floodwater	10–56
	Broadcast into floodwater and incorporated	10–43
	Incorporated before flooding	5–16
	Broadcast 12 days after transplanting	21
	Broadcast at panicle initiation	3

ammonia compensation point, which is a finite ammonia concentration in the intercellular air spaces of plant leaves. Plants absorb or lose ammonia depending on whether the ambient ammonia concentration is above or below the compensation point. Ammonia losses of about $1 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ have been determined from fields of barley, maize, and wheat.^[1]

Biomass Burning

During combustion, considerable plant nitrogen is converted into gaseous forms including ammonia. Most biomass burning (~90%) occurs in the tropics as a result of forest clearing, savanna and sugarcane fires, and burning of agricultural wastes and firewood. According to Intergovernmental Panel on Climate Change,^[5] 8700 Mt of biomass is burned every year, and agriculture accounts for half of this. About 4% of the biomass nitrogen is released as ammonia during combustion, with the result that biomass burning contributes between 4.5 and 5.9 Mt N per yr^{-1} globally to the atmosphere.^[6,7]

GLOBAL SIGNIFICANCE

The global emission of ammonia was estimated to be 54 Mt N yr^{-1} in 1990.^[7] The contributions from the major sources were given as: 1) excreta from animals, 21.7 Mt; 2) synthetic fertilizers, 9.0 Mt; 3) oceans, 8.2 Mt; 4) biomass burning, 5.9 Mt; 5) crops, 3.6 Mt; 6) human population and pets, 2.6 Mt; 7) soils under natural vegetation, 2.4 Mt; 8) industrial processes, 0.2 Mt; and 9) fossil fuels, 0.1 Mt. About half of the global emission originates in Asia, and approximately 70% is associated with food production.

When ammonia is emitted into the atmosphere, some is absorbed by vegetation, some is dissolved in atmospheric water, converted to aerosols and transported long distances (>1000 km), and some is deposited nearby.^[4,8] Model estimates indicate that about 50% of the emitted ammonia is deposited within 50 km of the source.^[8] High ammonia concentrations close to point sources such as cattle feedlots can damage vegetation, and deposition of ammonia and ammonium can result in acidification of soils and lakes, increased carbon storage in pristine areas, and increased emission of the greenhouse gas nitrous oxide;^[9] measures need to be instituted to reduce losses.

MITIGATION

Techniques proposed for reducing loss of ammonia from animal slurries applied to soils include incorporation or injection of the slurry into the soil, application with trail

hoses, acidification before application, applying during rainfall, at night, or in winter, and matching nitrogen supply to the demand of the crop. Decreasing the water content of the slurry and delaying application until a substantial canopy has developed (to reduce wind speeds) would also appear to have a large impact on ammonia loss.^[10] A logical option for limiting ammonia volatilization from cropping systems is to drill the fertilizer into the soil. Other recommendations include spreading the fertilizer just prior to rain, application in irrigation water, optimizing split application schemes, changing the fertilizer type to suit the conditions, and better matching of nitrogen supply with crop demand. Controlled release fertilizers provide an opportunity to match supply and demand while protecting the remainder of the fertilizer from release. Adoption of some or all of these practices will allow the farmer to reduce inputs and reduce the impact on the environment.^[5]

Amoozometer

Aziz Amoozegar

Soil Science, North Carolina State University, Raleigh, North Carolina, U.S.A.

Abstract

Hydraulic conductivity, defined as a measure of the ability of soil to transmit water, is an important dynamic soil property that is needed to solve agricultural, hydrological, and environmental problems. Since unsaturated hydraulic conductivity (K_{unsat}) measurements are difficult and time-consuming, saturated hydraulic conductivity (K_{sat}) is used to estimate K_{unsat} or assess water flow in the vadose zone using mathematical models. The constant-head well permeameter method is the most versatile procedure for determining K_{sat} in the vadose zone. In this procedure, the steady-state rate of water flow into the soil at the bottom of a cylindrical hole of known diameter ($2r$) under a constant depth of water (H) is measured, and K_{sat} is calculated using an appropriate model. The Amoozometer is a portable and easy-to-use permeameter for measuring K_{sat} of the vadose zone from the soil surface to 2 m depth. Measurements can be performed using a 4–10 cm diameter auger hole without excavating a pit. Using an additional set of constant-head tubes, measurement depth can be increased to 4 m. The Amoozometer has a 5-L water capacity and can be used on any landscape position. The Glover model, developed based only on the saturated water flow from the hole, is recommended for calculating K_{sat} because it is simple, does not require estimation of any soil property, and results in consistent values for all conditions. In addition, the Glover model compares well with other models that consider both saturated and unsaturated flow for H/r values ≥ 5 .

INTRODUCTION

Water flow through the saturated and unsaturated zones, governed by Darcy's law, is one of the major components of the hydrologic cycle. Water transmission is one of the most important dynamic processes in the soil, and it impacts many of the soil's properties and processes. Hydraulic conductivity is defined as a measure of the ability of soil to transmit water. It is also the proportionality factor in Darcy's law relating flux density or flux to the hydraulic gradient. Unsaturated hydraulic conductivity (K_{unsat}) depends on soil water content (θ) or pressure head (h); i.e., $K_{\text{unsat}} = K(\theta)$ or $K(h)$; however, obtaining a complete unsaturated hydraulic conductivity curve will be impractical for most applications. As an alternative, saturated hydraulic conductivity, generally denoted as K_{sat} (or K_s), is used in mathematical models to estimate K_{unsat} for modeling purposes.^[1] Although soil hydraulic conductivity is a highly variable soil property, K_{sat} can be taken to be a constant for a given time and space within the soil, and its value for the vadose (unsaturated) zone is often needed to solve many agricultural, hydrological, and environmental problems. Examples include designing a drainage system for controlling seasonal high water table and determining groundwater mounding under wastewater application areas or retention ponds. For most practical applications, K_{sat} of the vadose zone from the soil surface to depths exceeding a few meters can be measured conveniently by the constant-head well permeameter method using an Amoozometer.

CONSTANT-HEAD WELL PERMEAMETER METHOD

There are a number of procedures for *in situ* determination of soil K_{sat} above a water table (in the vadose zone) and below a water table (within an aquifer).^[2,3] The constant-head well permeameter method, also known as the shallow well pump-in technique or the borehole permeameter method, is perhaps the most versatile procedure used throughout the world for measuring the K_{sat} of the vadose zone. This procedure is completed in two steps; field measurement of the steady-state water flow rate into the soil through a cylindrical hole under a constant head and calculation of the K_{sat} using an appropriate model. For field measurement, a cylindrical hole of known radius (r) is dug to the desired depth. After establishing a constant depth of water in the hole, referred to as head of water (H), the steady-state rate of water flow from the hole into the soil (Q) is measured for calculating K_{sat} . A constant head of water at the bottom of the hole can be maintained using a small float,^[4] or a Mariotte bottle system.^[2,3,5] The Amoozometer (Fig. 1), also known as the compact constant-head permeameter (CCHP),^[6] is an instrument that can be used to measure K_{sat} by this procedure.

DESCRIPTION OF THE AMOOZEMETER

The Amoozometer is a portable, versatile, and easy to operate device that performs two functions: it maintains a

Fig. 1 Photograph of the Amoozometer.

Source: Photo courtesy of Ksat, Inc.

constant depth of water at the bottom of a cylindrical hole, and allows measurements of the rate of water entering the hole (equal to the rate of water infiltrating the soil at the bottom of the hole). With an Amoozometer, K_{sat} can be measured from the soil surface to 2 m depth without excavating a pit. Using an additional set of constant-head tubes (an accessory), the depth of measurement can be easily extended to 4 m.

An Amoozometer (hereafter referred to as CCHP) is composed of a set of four constant-head tubes, a 4-L water reservoir, a flow-measuring reservoir, a water-dissipating unit, and a base that houses a three-way valve that connects the two reservoirs and the water-dissipating unit together (Fig. 2).

The four constant-head tubes are based on the Mariotte principle and are constructed of clear polycarbonate tubing. They develop up to -200 cm of constant water pressure (vacuum) for maintaining the water level in an auger hole at a fixed distance below the device placed next to the hole on the land surface. Each constant-head tube is equipped with a “bubble tube” and must be filled with clean water (Fig. 2). The bubble tube in the first constant-head tube is adjustable and provides from 0 to -50 cm of water pressure. The bubble tube in each of the other three

Fig. 2 Schematic diagram of the Amoozometer.

Source: Photo courtesy of Ksat, Inc.

constant-head tubes is fixed and provides approximately -50 cm of water pressure. During operation, the height of water above the end of the bubble tube in each of the fixed constant-head tubes is approximately 50 cm. The negative pressure (up to -200 cm of water), corresponding to the desired distance between the level of water in the auger hole and the reference level on the base of the CCHP placed at the soil surface, is obtained by serially connecting an adequate number of constant-head tubes and adjusting the bubble tube in the first constant-head tube.

The 4-L reservoir at the center of the CCHP is constructed of durable polyvinyl chloride (PVC) pipe. It maintains the center of gravity above the middle of the base of the unit. The flow-measuring reservoir is constructed of clear polycarbonate tube and is equipped with a bubble tube. The tip of this bubble tube is set at a fixed position in the reservoir and is used as the reference level for maintaining a constant depth of water at the bottom of the hole. These two reservoirs are connected at the bottom through a three-way valve housed inside the base of the device. A large opening on top of the 4-L reservoir allows rapid filling of the CCHP with water. For operation, the bubble tube in the flow-measuring reservoir is connected to the series of constant-head tubes, and the tops of the two reservoirs are connected together to allow the air pressures above the water levels in the reservoirs to be the same.

The outlet of the three-way valve is connected to a water-dissipating unit through a 2.5-m long flexible plastic tubing (Fig. 2). The water-dissipating unit allows water to

be applied to the bottom of the hole uniformly without scouring the auger hole wall. A metal ring at the end of the water-dissipating unit minimizes the blockage of the bottom of the (cylindrical) hole during measurements.

The constant-head tube set for increasing the depth of measurement to 4 m below the land surface is similar to the setup of the four constant-head tubes on the CCHP. The only difference is that all the four bubble tubes are fixed, and each constant-head tube provides pressure equal to approximately -50 cm of water. For measurements, an adequate number of constant-head tubes from the set are serially connected to the four constant-head tubes on the permeameter on one side and to the flow-measuring reservoir on the other. In addition, for measurements below 2-m depth, the flexible tubing that connects the water-dissipating unit to the three-way valve is replaced with a 4.5-m long flexible plastic tube.

FIELD DATA COLLECTION

In addition to the CCHP, a set of augers, measuring tape, stopwatch, data sheet (Fig. 3), small shovel, and more than 5 L of water are needed. At the location of interest, an auger hole of known diameter ($2r$) is dug to the desired depth. A 6-cm diameter hole is highly recommended, but auger holes ranging from 4 to 10 cm in diameter can be used depending on the application and type of soil. (A large diameter hole should only be used in a soil horizon that is thick and has a relatively low K_{sat} .) A larger hand auger or a mechanical auger can be used to dig the hole to approximately 50 cm above the desired depth. The bottom 50 cm of the hole must be dug using a hand auger capable of boring the hole with the desired diameter. After digging the hole to the desired depth, a planer auger of the same diameter as the auger is used to cut the bottom of the hole and form a cylindrical-shaped cavity. A round nylon brush or another device^[3] may be used to remove smearing from the auger hole sidewall. Under certain conditions (e.g., the soil being too wet), however, brushing the hole may not reduce smearing. Various sizes of augers, planer augers, and brushes are commercially available.

The CCHP is placed on a flat area next to the auger hole, and the vertical distance from the bottom of the hole to the reference level on the CCHP is measured (distance D in Fig. 4). After selecting the desired depth of water in the hole (H), an adequate number of constant-head tubes are serially connected to the flow-measuring reservoir, and the bubble tube in the first constant-head tube is adjusted such that the cumulative distance between the tip of the bubble tube and the water level in the constant-head tubes in the series equals the distance from the reference level on the CCHP to the desired water level in the hole (distance d in Fig. 4). In Fig. 4, the proper connections of the constant-head tubes and the flow-measuring reservoir for measurements between a 100 and 150 cm depth are shown. Leaving the

top of the 4-L reservoir open, the three-way valve is fully opened to fill the flexible tube of the water-dissipating unit with water from both reservoirs. Then, after closing the three-way valve, and connecting the tops of the two reservoirs together, the water-dissipating unit is inserted to the bottom of the hole and the three-way valve is fully opened to allow water from both reservoirs to fill the hole. Shortly thereafter, a constant depth of water will be established in the hole. Finally, the adjustable bubble tube is used to adjust the depth of water in the hole to the desired level. At this point, all measured data are recorded in the data sheet (Fig. 3).

Water is allowed to move from the hole into the soil until a steady-state flow rate is achieved. If the flow rate of water into the hole is small (e.g., 50 cm³/hr), the three-way valve is turned to the flow-measuring reservoir only for more accurate measurements of water flow from the CCHP. The depth of the water in the hole must be checked (through checking distance d) frequently to make sure that a constant depth of water is maintained in the hole. For most practical applications, the steady-state condition is reached when three consecutive measurements of the flow rate under a constant depth of water are the same. After determining the steady-state infiltration rate, the K_{sat} value is calculated using the Glover equation or another appropriate model.

MODELS FOR CALCULATING K_{SAT}

There are a number of models for calculating K_{sat} using field data.^[3,4,7-10] One of the simplest models for calculating K_{sat} is the Glover equation:^[7]

$$K_{sat} = \left\{ \sinh^{-1} \left(\frac{H}{r} \right) - \left[\left(\frac{r}{H} \right)^2 + 1 \right]^{1/2} + \frac{r}{H} \right\} \frac{Q}{(2\pi H^2)} \quad (1)$$

where r , H , and Q are as defined before, and $\sinh^{-1}$ is the inverse hyperbolic sine function. This equation is for cases where the distance between the bottom of the hole and an impermeable layer below the hole (distance s in Fig. 4) is $\geq 2H$. To use the Glover equation, Amoozegar^[11] has suggested that H/r must be ≥ 5 . When s is $< 2H$, the equation

$$K_{sat} = \frac{3Q \ln \left(\frac{H}{r} \right)}{\pi H (3H + 2s)} \quad (2)$$

can be used for calculating K_{sat} . In Eqs. 1 and 2, r , H , and s have units of length (e.g., cm), Q has units of volume over time (e.g., cm³/hr), and K_{sat} has units of length over time (e.g., cm/hr).

The Glover model, Eq. 1, is based only on the saturated flow around the hole. Some of the other models, on the other hand, consider both saturated and unsaturated flow of water away from the hole. Stephens and Neuman^[10] presented an empirical equation based on saturated-unsaturated flow

through isotropic soils for estimating K_{sat} in a vadose zone with deep water table. Philip^[8] and Reynolds, Elrick, and Clothier^[9] used similar assumptions and developed models for calculating K_{sat} using the empirically developed equation relating the unsaturated hydraulic conductivity $K(h)$ to K_{sat} by^[1]

$$K(h) = K_{sat} \exp(\alpha h) \quad (3)$$

where h is the soil water pressure head and α (units of length^{-1} , e.g., cm^{-1}) is a measure of capillary properties of the soil, referred to as the sorptive number. For

determining K_{sat} , the parameter α must be determined independently or be estimated based on the soil texture and structure.^[12,13] One of the approaches for determining K_{sat} by the Reynolds, Elrick, and Clothier^[9] model is the simultaneous equation approach.^[3] Amoozegar^[11] and Salverda and Dane^[14] have shown that this approach is unreliable because it may result in negative K_{sat} values. Estimating α based on soil properties also may result in errors if the operator misestimates the soil properties in the field. Based on the author's evaluation, the Glover model, used when H/r is ≥ 5 , results in K_{sat} values that are very close to the calculated values by Philip^[8] and Reynolds, Elrick, and Clothier^[9] models for most practical applications. Considering the assumptions made for the later models (e.g., isotropic conditions and formation of a saturated bulb around the hole) and similarity between the calculated K_{sat} values, the Glover model is recommended for calculating K_{sat} because it is simple and results in consistent hydraulic conductivity values. Figure 3 shows field data and the calculated K_{sat} for one measurement at a site near Raleigh, North Carolina. For this measurement, radius of the hole $r = 3$ cm, the constant depth of water in the hole $H = 15.5$ cm, and the steady-state rate of water flow into the hole $Q = 504$ cm^3/hr . Plugging these values in Eq. 1, the calculated $K_{sat} = 0.51$ cm/hr or 12.2 cm/d.

COMPARISON OF METHODS FOR MEASURING K_{SAT}

Hydraulic conductivity is a highly variable soil property with coefficient of variation ($100 \times \text{SD}/\text{mean}$) that generally exceeds 100%. Also, because of the dynamic nature of water flow in soils, and differences in the soil volume involved in various *in situ* hydraulic conductivity measurement procedures, it is impractical to choose a field method as the benchmark procedure for measuring K_{sat} . Schoeneberger, Amoozegar, and Buol^[15] reported the *in situ* K_{sat} of

Table 1 Arithmetic mean, SD, and number of observations (n) for saturated hydraulic conductivity (K_{sat}) of three horizons of a Cecil soil at three landscape positions measured *in situ* under 15 cm head and determined in the laboratory using intact core samples collected in vertical orientation.

three different horizons of a Cecil soil (a clayey, kaolinitic, and thermic Typic Kanhapludult), measured at three different geomorphic (landscape) positions under 15 and 25 cm heads using the Amoozometer and the Glover model (Eq. 1), along with the laboratory measured K_{sat} of intact core samples collected from the same horizons in different orientations. The *in situ* results for 15 cm head and laboratory-determined vertical K_{sat} reported by them are presented in Table 1. Their results showed good agreement between laboratory and *in situ* determined K_{sat} values for saprolite (C horizon) with no soil structure and few tubular pores or planar voids. The average laboratory values for the Bt horizon containing tubular and planar voids, on the other hand, were consistently higher than the corresponding *in situ* values. For the B/C horizon, although the average values for *in situ* K_{sat} were numerically higher than the corresponding values for cores, there were no significant differences between the *in situ* and laboratory measured K_{sat} for all three landscape positions.

CONCLUSION

The constant-head well permeameter method is perhaps the best procedure for measuring saturated hydraulic conductivity (K_{sat}) of the vadose (unsaturated) zone. The Amoozometer is a portable and versatile device that allows measurement of K_{sat} by this procedure from the soil surface to depths exceeding a few meters using only a small diameter hole. The device is constructed of durable materials, does not require field assembly, and is easy to use. The soil K_{sat} at the depth of interest can be calculated using the relatively simple Glover model. For most practical applications, K_{sat} can be measured in 1–3 hours using less than 5 L of water.

ACKNOWLEDGMENTS

The original research and development of Amoozometer were supported by the North Carolina Agricultural Research Service. The use of trade name in this entry does not imply endorsement by the North Carolina Agricultural Research Service of the product named or criticism of similar ones not mentioned.

Anaerobic Processes

Paul A. McDaniel

Daniel G. Strawn

University of Idaho, Moscow, Idaho, U.S.A.

Abstract

Anaerobic processes in soils occur when available molecular oxygen concentrations are limited. These processes include a myriad of biogeochemical processes that typically occur in soils that are saturated with water for extended periods. Anaerobic processes result in soil characteristics such as increased organic matter content, changes in biological activity, and formation of redoximorphic features.

INTRODUCTION

Availability of oxygen (O_2) in soils, or lack thereof, has a profound effect on soil biogeochemical processes. When molecular O_2 is absent in soils or present in very small quantities, anaerobic biological processes occur that create distinct soil chemical properties and morphological features as compared to aerobic soils.

ANAEROBIC CONDITIONS AND O_2 AVAILABILITY

A common means of assessing O_2 status of soils is measuring redox potential (E_h). E_h can be thought of as a measure of the electron activity of a system.^[1] E_h can be predicted using theoretical relationships or measured directly in the soil using a redox electrode. The exact relationship between O_2 and E_h within soils is dependent upon a number of specific soil properties; the general relationship illustrated in Fig. 1 shows that as O_2 levels in soils decline, E_h decreases (provided biological respiration is occurring). Levels of O_2 availability in soils are generally described using three categories (Fig. 2):

- *Oxic* or *aerobic* soils— O_2 is readily available; E_h range of ~300–800 mV at pH 7.
- *Suboxic* soils—limited O_2 availability; E_h values of ~100–300 mV at pH 7.
- *Anoxic* or *anaerobic* soils— O_2 is absent or otherwise unavailable to organisms (may occur in localized zones of the soil); E_h values less than ~100 mV at pH 7.

It is important to note that in soils, anaerobic conditions may occur on a microscale. The O_2 content of soil aggregates may change dramatically across a distance of a few millimeters.^[5] Due to slow gas exchange, the centers of wet aggregates as small as 8 mm in diameter can remain anaerobic even when dried and exposed to ambient air O_2 concentrations.

While the O_2 content of earth's atmosphere is approximately 21%, the O_2 content in soil air is typically lower. The main reservoir of O_2 in soils is air that occupies pore spaces between mineral particles, but O_2 is also dissolved in soil water. The gaseous and dissolved O_2 present in soils serves a critical biological function—it is consumed during aerobic respiration by soil microorganisms and by the roots of most plants. In aerobic respiration, organisms obtain energy through the oxidation of organic substrates, a process whereby electrons are passed through a series of carriers and ultimately accepted by O_2 .^[6]

DEVELOPMENT OF ANAEROBIC CONDITIONS

Several factors contribute to the decrease in O_2 availability and the development of anaerobic conditions in soils. Aerobic respiration consumes O_2 and generates carbon dioxide (CO_2). Therefore, without rapid gas exchange between the soil and the atmosphere, the soil atmosphere will become depleted in O_2 and enriched in CO_2 . The rate of gas exchange is dependent upon soil texture, structure, and the quantity, size, and connectivity of soil pores.^[7] In general, slower gas exchange occurs in fine-textured soils and those with poor soil structure. As soils become very wet and approach saturation, air is physically excluded from soil pores, thereby reducing the amount of air present and inhibiting gas exchange. The amount of O_2 that can be dissolved in soil water decreases as water temperature increases. Soil temperature also affects microbial activity in soils, and thus temperature is a key factor controlling soil redox processes.

ANAEROBIC CONDITIONS AND BIOLOGICAL ACTIVITY

Most plants are adversely affected by anaerobic conditions because root respiration decreases, thereby limiting

growth. As a result of decreased root activity, the uptake of water and nutrients also decreases.^[7] Some plants, however, have developed special adaptations to anaerobic soils and can transport O_2 from the aboveground into the roots.

When O_2 becomes limiting in soils, microbial populations shift to organisms capable of anaerobic and fermentative respiration, and soils become anaerobic.^[6] During anaerobic respiration, organisms use alternative electron acceptors. In soils, these are typically nitrogen,

manganese (Mn), iron (Fe), and sulfur (S). The E_h at which these reduction reactions occur in soils is dependent on a number of variables, including pH and the form of the element that is present. The theoretical E_h values at which some of these reduction reactions occur at pH 7.0 are shown in Fig. 2. As E_h decreases, the theoretical sequence of terminal electron acceptor use is: NO_3^- , Mn^{4+} , Fe^{3+} , and SO_4^{2-} .

A second consequence of the change in microbial activity from aerobic to anaerobic conditions is that the biodegradation of soil organic material decreases. Under aerobic conditions, the decomposition of organic materials can proceed rapidly.^[8] However, as the O_2 supply becomes limited, organic matter decomposition occurs via anaerobic respiration and fermentation. These are less efficient metabolic processes, resulting in slower decomposition of organic substrates. In soils with limited O_2 availability, this leads to a greater net accumulation of organic matter.

ANAEROBIC REACTIONS IN SOILS

Utilization of alternative or secondary electron acceptors during anaerobic respiration causes important changes in the speciation and behavior of many soil chemicals. Reduction of NO_3^- , Mn^{4+} , Fe^{3+} , SO_4^{2-} , and CO_2 are common reactions that occur in anaerobic soils. Possible half reactions for reduction of these species are

The electrons in these reactions come from an oxidizing reaction, typically heterotrophic oxidation of reduced carbon (i.e., $CH_2O + H_2O = CO_2 + 4e^- + 4H^+$). The half reaction involving nitrogen is a summary reaction that involves several steps and the formation of a variety of compounds, including NO_2^- , N_2 , and nitrous oxide (N_2O).^[9] Loss of gaseous nitrogen as N_2 or N_2O , a process known as denitrification, reduces nitrogen availability for plant uptake and is a concern for agriculture management of flooded soils such as rice paddies and other soils that have high water tables.

The reduction of insoluble mineral forms of Mn and Fe to soluble forms is characteristic of low- O_2 conditions.^[10] The half reactions shown for reduction of Mn oxide and goethite ($FeOOH$) are reductive dissolution reactions. Reduced Fe^{2+} and Mn^{2+} are much more soluble than the oxidized species, and therefore mobile in anaerobic soils, forming zones of Fe and Mn depletion and enrichment. As a result, reduction reactions involving Fe and Mn are of particular significance because they result in the formation of observable morphological

features that can be used as indicators of anaerobic conditions.

Reduction of SO_4^{2-} occurs at low E_h conditions in soils and will typically give rise to sulfide [hydrogen sulfide (H_2S), HS^- , or metal sulfide minerals].^[10] In flooded soils, H_2S gas that is released has a rotten egg smell.

At extremely low E_h conditions, the fermentation of organic compounds produces CO_2 and methane (CH_4).^[3,6] Methanogenesis, the formation of CH_4 , can occur by multiple pathways, one consuming hydrogen and CO_2 (shown in the half reaction above).

Other elements not listed above are also susceptible to reduction in soils under low E_h conditions, thereby changing their speciation and solubility. This is particularly important for many trace elements in soils such as selenium [$\text{Se(VI)} \rightarrow \text{Se(IV)} \rightarrow \text{Se(0)} \rightarrow \text{Se(-II)}$], arsenic [$\text{As(V)} \rightarrow \text{As(III)}$], chromium [$\text{Cr(VI)} \rightarrow \text{Cr(III)}$], and mercury [$\text{Hg(II)} \rightarrow \text{Hg(I)} \rightarrow \text{Hg(0)}$]. In anaerobic soils contaminated with these elements, reduction dramatically changes their behavior.

ANAEROBIC CONDITIONS AND SOIL MORPHOLOGY

Anaerobic conditions associated with water tables and saturated conditions are often seasonal occurrences in soils. Field scientists therefore commonly rely on soil morphological features as indicators of seasonal anaerobic conditions and by extension, high water tables. Two features commonly used for this purpose are the color patterns created by Fe and Mn compounds and the accumulation of soil organic matter.^[9]

The microbial reduction of Fe and Mn that occurs under conditions of limited O_2 is a critical step in the formation of redoximorphic features. Redoximorphic features result from alternating periods of reduction and oxidation of Fe and Mn compounds in soils.^[11] As Fe and Mn are reduced, they form soluble and generally colorless compounds. In the more mobile reduced state, Fe and Mn are subjected to redistribution and, in some cases, are removed from soils. As soil water moves to more oxidizing zones or the soil dries out, Fe and Mn are reoxidized and precipitate out of soil solution, giving rise to distinct zones of depletion and accumulation. Under oxidizing conditions, various oxide forms of Fe impart characteristic red, yellow, and brown colors to soils. The zones of Fe and Mn enrichment and depletion are referred to as redox concentrations and redox depletions.^[11] Redox depletions appear as low-chroma, grayish zones from which Fe and Mn have been at least partially removed. Redox concentrations appear as brightly colored soft masses or hard nodules composed of Fe and Mn oxide forms (Fig. 3A and B).^[11]

Localized zones of clay depletion are also indicative of anaerobic conditions and associated processes.^[12] These

Fig. 3 (A) Close-up view of redox concentrations and redox depletions in a seasonally anaerobic soil. The mottled color pattern consists of gray redox depletions and reddish-orange redox concentrations. Field of view is approximately 10 cm across. (B) Morphological expression of anaerobic conditions in an Aquult from the southeastern United States. The thick, dark surface layer reflects the accumulation of organic matter. Note gray subsoil colors. Scale shows depth in feet and centimeters.

depletions typically have lighter and/or grayer colors than the soil matrix, reflecting the loss of pigmenting agents such as Fe and Mn oxides and clays.^[12] Layer silicate clays are degraded by the alternating oxidation and reduction of Fe compounds, a process known as ferrolysis.^[13] As a result, these zones of clay depletion contain less clay than does the soil matrix.

Under strongly anaerobic conditions, the soil matrix is reduced and appears dull gray and may exhibit a bluish or greenish tint—these are referred to as gray colors. Upon exposure to air, these reduced matrices may develop brighter colors as Fe oxidizes.^[9,12]

Cycling and turnover of organic materials are directly related to O_2 availability in soils. Biodegradation of organic residues is inhibited under anaerobic conditions, and organic matter may accumulate rapidly under such conditions. This results in the formation of a very dark surface horizon in mineral soils (Fig. 3B). Under more prolonged anaerobic conditions, organic materials may accumulate to the extent that soils are classified as organic soils (Histosols). Histosols contain a minimum of 20% organic matter on a weight basis to a depth of at least 40 cm.^[11] These soils typically occupy the wettest landscape positions, such as depressions and low-lying areas with high water tables.

CONCLUSION

Anaerobic processes in soils occur when O_2 concentrations are limiting. These biogeochemical processes are typically associated with soils that are saturated with water for extended periods of time. Anaerobic processes include the biologically mediated reduction of Fe and

Mn and subsequent formation of distinctive morphological features that are used by soil scientists to infer hydrological conditions. Changes in microbial activity also occur with anaerobic conditions and lead to the accumulation of organic matter.

Andisols

Jon Chorover

*Department of Soil, Water and Environmental Sciences, University of Arizona,
Tucson, Arizona, U.S.A.*

Abstract

Andisols are deep soils of low bulk density that are most often derived from volcanic parent materials. They are classified on the basis of unique mineralogical, chemical, and physical properties. This soil order, which is most prevalent along the tectonically active Pacific Ring of Fire, covers approximately 120 million hectares or 1% of the earth's surface. Andisols are capable of supporting agricultural production and human populations that are large relative to the spatial extent of the soils. The prefix, "An," refers to the dark color of the surface horizon(s) that results from high concentrations of humified organic matter stabilized by chemical interaction with poorly crystalline secondary minerals. The morphology of the soils typically includes multiple sequences of A and Bw horizons that are buried successively because of intermittent deposition events.

CLASSIFICATION OF ANDISOLS

The classification of Andisols^[1] proposed by Smith^[2] and was refined through the efforts of the International Committee on the Classification of Andisols. Parent material must be weathered to fall within a range of characteristics pertaining to bulk density, particle size, phosphorus adsorption capacity, and within a range of mass concentrations of organic carbon (C), volcanic glass, and oxalate extractable iron (Fe) and aluminum (Al).^[1] Specifically, the soil material must contain no more than 250 g/kg organic C and either oxalate extractable $\text{Al} + 0.5 \text{ Fe} = 20 \text{ g/kg}$, bulk density (at 33 kPa) $= 0.9 \text{ Mg/m}^3$, and phosphate retention $= 85\%$, or phosphate retention $= 25\%$, particles between 0.02 and 2 mm in size $= 300 \text{ g/kg}$, oxalate extractable $\text{Al} + 0.5\text{Fe} = 4 \text{ g/kg}$, and volcanic glass in the 0.02–2 mm fraction $= 362 - 15.6 \times (\text{oxalate extractable } \text{Al} + 0.5\text{Fe})$, where all units are grams per kilogram. Soils classified as Andisols are, therefore, dominantly those developing in volcanic ash, pumice, cinders, and other volcanic ejecta. Suborders are based on climate regimes, whereas great groups and subgroups are based on soil physical–chemical properties such as clay and organic matter content.

PEDOGENIC FACTORS

Most Andisols develop from chemical weathering of volcanic ejecta in combination with organic matter humification.^[3] Common parent materials range, in physical form, from fine ash to viscous lava flows, and in mineralogical composition from andesitic and rhyolitic to basaltic rock types. Basalt weathers more rapidly than andesitic rock

and, because of the availability of reactive surface, finely divided ash weathers more rapidly than lava. Sufficient weathering of parent material is required to produce the poorly crystalline Al, Fe, and silicon (Si) compounds in the quantities needed to classify a soil as an Andisol. Thus, these soils commonly occur in humid regions.^[4] Andisols are formed from parent materials other than volcanic ejecta, provided that sufficiently high levels of reactive Al, Fe, and organic matter are present, but volcanic parent materials are most common. The high specific surface area and reactivity of poorly crystalline minerals result in greater organic matter retention than occurs in most other soil orders except Histosols. The sequence of soil horizons is typically A–Bw–C (Fig. 1). The surface A horizon often contains very high concentrations of organic matter (typically greater than 100 g/kg) that is stabilized by complexation with Al and Fe. The B horizon is normally dominated by poorly crystalline aluminosilicates and hydrous oxides (allophane, imogolite, and ferrihydrite). Periodic eruptions in volcanically active areas can produce a series of buried A–Bw sequences, which is one cause of deep humus penetration in Andisols.^[5] This factor also contributes to the significant depth of Andisol profiles.

PHYSICAL–CHEMICAL PROPERTIES OF ANDISOLS

Mineralogy

The unique properties of Andisols are strongly linked to the chemical properties of constituent solid phases.^[4,6] Primary silicate minerals in andesitic and rhyolitic flows

Fig. 1 Schematic representation of a typical Andisol profile.

include quartz, hornblende, and biotite, whereas olivines, pyroxenes, and plagioclase are more common in basalts. Rapid weathering of volcanic ejecta (containing aluminosilicates, volcanic glass, and smaller amounts of ferromagnesian minerals) results in the accumulation of soluble silica, Al, and Fe to high concentrations in the soil solution of young Andisols. In the near surface (e.g., A horizon), Fe and Al are often immobilized into humic complexes, whereas Si may polymerize to form opaline silica. At greater depth (e.g., Bw horizon), or if humus concentrations are low, hydrolysis and polymerization of Al, Fe, and Si result in precipitation of allophane ($x\text{SiO}_2 \cdot \text{Al}_2\text{O}_3 \cdot y\text{H}_2\text{O}$, where $x = 0.8\text{--}2$ and $y = 2.5$), ferrihydrite ($5\text{Fe}_2\text{O}_3 \cdot 9\text{H}_2\text{O}$), opaline silica ($\text{SiO}_2 \cdot n\text{H}_2\text{O}$), amorphous aluminum hydroxide [$\text{Al}(\text{OH})_3$], and/or imogolite ($\text{SiO}_2 \cdot \text{Al}_2\text{O}_3 \cdot 2.5\text{H}_2\text{O}$), depending upon solution composition. Allophane and ferrihydrite, which do not exhibit the long-range crystal structure necessary to yield well-defined X-ray diffraction patterns, are commonly termed short-range order (SRO) solids. These minerals and imogolite are "metastable" thermodynamically. That is, over the long term, Ostwald ripening of soil solids transforms SRO phases into more crystalline forms such as halloysite, goethite, and gibbsite. As the accumulation of more crystalline phases causes soil characteristics to diverge from those that are diagnostic for the Andisol order, Andisols represent an intermediate stage of pedogenesis, the lifetime of which depends on interacting state factors that control mineral transformation rates.

The important properties of Andisols are generally ascribed to the preponderance of allophane and X-ray amorphous compounds of Al, Si, and humus,^[2] but high concentrations of Al and Fe humus complexes can confer to non-allophanic soils, the key diagnostic properties that are common in allophanic Andisols.^[7] It is, therefore, recognized that important SRO minerals of Andisols include not only allophane but also imogolite, ferrihydrite, poorly crystalline $\text{Al}(\text{OH})_3$, and Al/Fe-humus complexes. The SRO minerals in Andisols exhibit very high specific surface areas (ca. $10^5\text{--}10^6 \text{ m}^2/\text{kg}$) and reactive site densities ($5\text{--}20 \mu\text{mol}/\text{m}^2$). Unit particles of allophane are roughly spherical and 3.5–5.5 nm in diameter, whereas imogolite appears as smooth and curved threads of 10–30 nm diameter, and ferrihydrite is composed of spherical particles of 3–7 nm in diameter.^[8,9]

Chemistry

Chemical properties of Andisols are dominated by the main pedogenic weathering products of volcanic debris in terrestrial ecosystems: X-ray amorphous SRO compounds of Al, Si, and Fe, and their complexes with organic matter.^[10] These constituents are the target species measured during acid ammonium oxalate treatment of the soil, and their prevalence is diagnostic for an Andisol. Humus concentrations correlate with SRO minerals and extend to depth accordingly. Allophane, imogolite, and ferrihydrite contain a prevalence of surface hydroxyl groups that: 1) retain and dissociate protons (H^+) in response to changes in soil solution pH and 2) can form strong complexes with humic substances and oxyanions such as phosphate.^[4,9] In particular, the strong binding of phosphate can lead to plant P deficiencies, when these soils are used for crop production. These surface reactions confer significant variable charge on the soils. With increasing pH, cation adsorption increases and anion adsorption decreases. The pH value where moles of adsorbed cation and anion charge are equivalent is termed the point of zero net charge (PZNC). The total surface charge at any point is a function of solution chemistry, soil mineralogy, and organic matter chemistry. In general, increasing amounts of Fe and Al oxides will increase the PZNC, whereas increasing amounts of SRO silica and organic matter will decrease it. Andisols contain relatively low quantities of 2:1 layer-type clay minerals and, therefore, permanent (structural) charge represents a small fraction of the total surface charge.^[11]

As SRO solids are more soluble than well-crystallized phases, they can support relatively high equilibrium concentrations of dissolved Al. The prevalence of Al in Andisols can maintain acidic soil pH (4.5–6.0) via Al hydrolysis reactions and diminish base saturation via displacement of non-hydrolyzing cations Ca^{2+} , Mg^{2+} , K^+ , and Na^+ from cation exchange sites. In addition, complexation with humic substances of monomeric, polymeric, and colloidal

forms of Al and Fe serves to coagulate and stabilize organic matter in Andisols, leading to long turnover times of organic C.^[12]

Physical Properties

Allophane, imogolite, ferrihydrite, and organic matter are responsible for the unique properties of soils derived from volcanic parent materials. The charge characteristics, size, and shape of these constituents are important determinants of soil physical properties. Andisols containing large quantities of SRO constituents have specific surface areas as high as $6 \times 10^5 \text{ m}^2/\text{kg}$. The density of allophane particles—ca. 2.7 Mg/m^3 —is slightly higher than more crystalline aluminosilicates such as kaolinite and montmorillonite. Therefore, the much lower bulk densities encountered in Andisols ($<0.85 \text{ Mg/m}^3$), where SRO minerals are dominant, are attributed to the high porosity of microaggregates formed, when unit particles interact with each other and with organic matter. Aggregation of SRO constituents, and their interaction with humic substances, gives rise to large void volumes (25–45%) in the micropore and mesopore size ranges. In conjunction with the significant quantity of hydration water associated with primary particles, this gives Andisols the capacity to retain as much as 1.8 kg water per kilogram soil solids and to support lush vegetation even at low rainfall. Hydraulic conductivity values are high because of low bulk density values and granular structure. Hydraulic properties can be altered by changing chemical conditions to induce dispersion of variable-charge soil colloids. For example, saturated hydraulic conductivity values can be reduced dramatically by displacing soil pH several units from the point of zero charge. Because of the hydrated nature of SRO phases and microaggregates, soil drying to high tensions results in irreversible changes to many of these soil physical properties. Physical properties of Andisols have been reviewed by Maeda and coworkers^[13,14] and Wada.^[10]

LAND USE AND MANAGEMENT

Andisols can provide exceptional media for plant growth in comparison to other mineral soils.^[4] They tend to have a thick solum with unrestricted rooting zones, high organic matter contents, and abundant available water. The supply of lithogenic nutrients is provided through rapid weathering of residual volcanic ash and lava. In regions of high rainfall, however, loss of cationic nutrients may be facilitated by intense leaching. Under such conditions, and as a result of reactive SRO mineral surfaces, the sustainable management of Andisols for agriculture and forestry may also be limited by phosphorus deficiency and low cation exchange capacity, among

other constraints. Nitrogen (N) availability may also limit plant production to the extent that N mineralization is limited by chemical stabilization of humus into metal–humus or mineral–humus complexes. The low bulk density, friable consistence, and granular structure, particularly in surface horizons, facilitate tillage operations such as seed-bed preparation and plowing. High porosity and plant available water favor seedling emergence, root development, and ramification. These soils resist compaction, even when cultivated continuously, and tend to regain physical properties after wetting and drying cycles once compacted by machinery. High hydraulic conductivities and water retention capacities promote infiltration and diminish erosive overland flow. Binding of SRO minerals and humic substances gives rise to strong soil aggregates that resist mechanical disruption by raindrops that could otherwise lead to particle detachment and erosion.

CONCLUSION

Weathering of volcanic ejecta under humid conditions results in supersaturation of soil solutions with respect to metastable, poorly crystalline aluminosilicates, $\text{Al}(\text{OH})_3$, and Fe hydroxides. Accumulation of these high specific surface area solids gives rise to the unique chemical and physical properties characteristic of the Andisol order. Organic C accumulations result from complexation with dissolved Al and Fe and from adsorption to the high surface area secondary minerals. Given the prevalence of weakly acidic functional groups associated with hydrous oxides and organic matter, Andisols exhibit variable surface charge properties that are highly dependent on solution pH and ionic composition. Andisols are also characterized by low bulk density and high water retention because of the extensive porosity of particle micro- and macroaggregates.

Andisols: Iceland

Olafur Arnalds

Agricultural Research Institute, Keldnaholt, Iceland

Abstract

Icelandic soils and their environment have some attributes seldom found in volcanic areas, such as steady eolian flux of basaltic tephra materials, intense cryoturbation, and extensive deserts in a humid environment, dominated by vitric surface materials. Soils of Icelandic wetlands are predominantly Andisols, but Histosols are of limited extent despite the subarctic climate. The objective of this entry is to give a brief overview of Icelandic soils and to describe the major factors shaping their development.

INTRODUCTION

The surface of Iceland is covered by volcanic soils, representing the largest area of such soils in Europe and perhaps >5% of Andisols in the world.^[1] Worldwide distribution of Andisols is generally related to volcanic parent materials, but they have also formed in older volcanic rocks reworked by glacial activity such as in central France.^[2] Andic soil properties, which define Andisols, result from the presence of short-range-order clay minerals such as allophane, ferrihydrite, and imogolite and the presence of metal–humus complexes. Vitric materials (tephra) are also used for the definition of Andosols.

PHYSIOGRAPHY

Iceland is a volcanic island of about 100,000 km² on the Mid-Atlantic Ridge. Temperature regime is mostly cryic as a result of subarctic oceanic and moist climate, with mild winters and cool summers. Many freeze-thaw cycles occur each winter, causing intense cryoturbation. Volcanic eruptions occur on average every 4–5 years and produce both solid lavas and volcanic tephra. Since glaciation during the Quaternary period, the surface of Iceland has been extensively mantled by eolian and tephra materials in which Andisols have developed. Lavas and glaciofluvial sediments also cover large areas. Most glacial sediments are mainly composed of volcanic glass.

Erosion has removed large proportion of the soils that formed in the eolian and tephra sediments, which has created large desert areas.^[3] For a more detailed description of the Icelandic physiography, please refer to Arnalds^[1] and the bibliography at <http://www.rala.is/desert>.

CLASSIFICATION AND SOIL CHARACTERISTICS

A new classification scheme for Icelandic soils^[1] is related to the Food and Agriculture Organization World Reference

Base (WRB) for soils,^[4] and it has been used for making a 1:500,000 soil map of Iceland (see www.rala.is/desert). The major soil types according to the system are Vitrisols, Histosols, Histic Andosols, Gleyic Andosols (GA), Brown Andosols (BA), and Leptosols (Table 1). The Andosol soil types have a single name in Icelandic, although two are used in English for clarity. Soil types under the Icelandic scheme are branded in italics to prevent confusion with WRB or Soil Taxonomy. The method of separating the soils acknowledges the dominant influence of three factors in shaping soil properties in Iceland: 1) the rate of eolian and tephra deposition; 2) the drainage; and 3) the presence of deserts with coarse-grained soils with low organic content.

The first two factors, eolian deposition and drainage, influence the amount and type of colloid materials (allophane, ferrihydrite, and metal–humus complexes) and the total organic content of the Andosols and Histosols. This relationship is shown in Fig. 1. Rapid eolian deposition tends to favor the formation of BA and reduces the organic content of the soils. Decreasing drainage (or permanent wetness) and slower eolian input lead to higher organic content with Histosols in wet positions that receive little eolian sedimentation.

When considering soil properties such as water retention and bulk density, the dominance of organic content becomes evident [Fig. 2; symbols grouped according to carbon (C) content]. Water retention at 15-bar suction is very high and reaches 300% in some organic horizon, but 15-bar water content is commonly 50–100% in the andic soil horizons (1.2–20% C). Vitric horizons with low organic content (<1.2% C) have relatively much lower 15-bar water content. The influence of organic matter (that includes metal–humus complexes) masks the influence of clays on the 15-bar water-holding capacity. Bulk density shows similar trend with the lowest bulk density of about 0.2 g cm⁻³ in organic horizons (>20% C). However, bulk density remains low in inorganic horizons with considerable clay content (allophane and ferrihydrite). Other soil properties are also typical of Andisols, such as high

Table 1 Extent of Icelandic soil types and complexes of soil types.

Soil type	Symbol	Extent (km ²)	Percentage of soils (%)
Histosols	H	1,090	1.2
Histic Andosols	HA	4,920	5.5
GA	WA	2,390	2.6
BA	BA	13,360	14.8
Leptosols	L	7,310	8.1
Cambic Vitrisols	MV	17,640	19.5
Arenic Vitrisols	SV	4,550	5.0
Cryosols and GA	C-WA	140	0.2
BA and GA	BA-WA	28,080	31.1
Cambic Vitrisols and Arenic Vitrisols	MV-SV	6,000	6.6
Arenic Vitrisols and Leptosols	SV-L	4,790	5.3
<i>Total</i>		<i>90,270</i>	<i>100</i>

Source: From Arnalds.^[1]

phosphate retention and cation exchange capacity, and most Icelandic soils have pH measured in NaF greater than 11.^[1]

Wetland Soils

The Andisols of Iceland include extensive wetland soils (>22,000 km²) that are characterized by both clays (allophane and ferrihydrite) and metal–humus complexes. Because of the dominance of andic materials when present

Fig. 1 Schematic figure showing the influence of drainage and eolian flux on properties and classification of Icelandic soils. BA are found in freely drained positions. They are vitric near active eolian sources, but have relatively high clay content (allophane, ferrihydrite, and imogolite) far from such sources. GA are found in poorly drained positions with high flux of eolian materials, but there is a gradient from poorly (with vitric GA) and andic GA to allophanic GA in somewhat poorly drained sites with little flux of eolian materials. As soils become less influenced by eolian input, soils become more Histic, with Histosols as the end member at wet sites far from eolian sources (lower left corner).

Fig. 2 (A) Water retention of Icelandic Andisols as a function of clay content. Horizons are grouped by organic C%. Organic soils have highest water retention, but some of the andic horizons with both high organic C content (12–20% C) and allophane (>2% Si₀) also have >100% 15-bar water content. Vitrisols with <1% Si₀ have the lowest water retention. (B) Bulk density of Icelandic Andisols as a function of clay content, horizons grouped by organic C%. Organic horizons (>20% C) have bulk density of about 0.2 g cm⁻³. Soils with low C% (vitric horizons) have low clay content and often relatively high bulk density (>0.8 g cm⁻³), but the soils have, in general, low bulk density characteristic of Andisols (predominately <0.8 g cm⁻³).

in soils, Andosols/Andisols can have up to 20% C if other criteria for andic properties are met according to the WRB,^[4] but 25% C according to Soil Taxonomy.^[5] The 20% limit is used in Iceland. Histosols, with >20% C, are found only far from active eolian sources and mostly on Tertiary bedrock, which has slow water permeability. Their extent (1.2%) is surprisingly low considering the subarctic location of Iceland and the great extent of wetlands. Histic Andosols (4920 km²) are wetland soils with high organic content (12–20% C), but in addition to organic matter, the colloid fraction is dominated by metal–humus complexes, allophanes, and ferrihydrite. Histic Andosols receive sufficient eolian input to lower the organic content below the 20% C diagnostic limit.

The GAs (estimated as 16,000 km²) are soils of wetlands with relatively low organic content in surface horizons

Fig. 3 The relationship between pH (measured in water) and allophane content in soils from 34 sites from all parts of Iceland. Surface horizons only, sampled from 0–5, 5–10, and 10–15 cm depth intervals. Soils with pH < 4.9 do not contain appreciable amounts of allophane.

(<12% C). Intense eolian input reduces the organic content and results in the formation of Andisols with properties dominated by allophane, ferrihydrite, and metal–humus complexes. GA are also found on young parent materials (fluvial and eolian) in poorly drained positions. The eolian input, with easily weathered basaltic tephra, recharges the system with bases, resulting in relatively moderate pH of 6–7, which favors the formation of allophane. Soil reaction is lower in the Histic Andosols and Histosols, where the formation of metal–humus complexes dominates. Our data indicate that the formation of allophane is clearly hindered when pH is lower than 4.9 (Fig. 3), as has been shown for Andisols elsewhere.^[6]

Freely Drained Soils

The BA are the typical freely drained Andisols of Iceland, containing appreciable amounts of allophane and ferrihydrite (total of 10–40%).^[1,7] These soils often contain dark basaltic and light-colored rhyolitic tephra that have been dated.

The soils of Icelandic deserts are predominately Andisols according to Soil Taxonomy.^[8] However, the desert soils are classified either as Andosols or as Leptosols according to the WRB, which requires a minimum soil depth for Andosols, resulting in Leptosol classification of shallow soils. These soils have different characteristics and functions from the Andosols and Histosols (Icelandic classification scheme). The great extent (> 30,000 km²) and uniqueness warrant their separation at the highest level of the Icelandic classification scheme as Vitrisols. The Vitrisols are coarse grained, with low contents of allophane and organic matter. Nitrogen levels are low,

making the reestablishment of vegetation difficult, but low water-holding capacity and intense frost action also contribute to their infertility. Future work is likely to result in further division of the Vitrisols into 2–3 categories comparable to those used for Andosols according to the Icelandic scheme, as is performed in Table 1.

Leptosols (9700 km²) are mainly very thin soils (1–10 mm) of (Holocene) lava fields that lack the eolian mantle in which Andosols form. They also include extensive scree slopes in mountainous areas.

VITRISOL CLASSIFICATION PERSPECTIVES

Central to classification of Andisols/Andosols in Soil Taxonomy^[5] and the WRB^[4] is the determination of their colloidal constituents by acid oxalate extraction of aluminum (Al), iron (Fe), and silica (Si; Al_o, Fe_o, and Si_o). Andisols have >2% Al_o + (1/2)Fe_o. The presence of vitric materials (various types of tephra) is also recognized by lowering this limit to as low as 0.4%, depending on the abundance of vitric materials. Most of the Icelandic Vitrisols meet the > 0.4% Al_o + (1/2)Fe_o criterion for Andisols, but this limit seems arbitrary in Iceland, and it can be doubted that it does provide meaningful separation of soils with abundance of vitric materials. On a world basis, vitric soils are poorly accounted for and recognized as weakly developed soils or parent material (tephra), with [Al_o + (1/2)Fe_o] < 0.4%. The uniqueness of these parent materials is recognized in some other classification systems such as for New Zealand with “Pumice Soils.”^[9]

ANDIC SOILS AND CRYOTURBATION

Cryoturbation occurs with great intensity in Iceland.^[1,10] The evidence is seen by cryoturbation in the soils and as various surface features such as “thufur” (hummocks) and a variety of active solifluction features. Cryoturbation in Iceland is enhanced by several factors. Water is pumped from shallow water table in wetlands. Freeze-thaw cycles are numerous, and the soil temperature stays near 0°C for extensive periods, which enhances stationary freezing front. The physical properties of Andosols are important as well. Both saturated and unsaturated hydraulic conductivity of the soils are rapid, which enhances water transfer to the freezing front. The great water-holding capacity (often >40% at 15-bar suction in freely drained soils) also contributes water that freezes in the soil. An additional factor is the thixotropic nature of many soils, as this allows easy deformation of the soil by the ice formation.

SOIL EROSION

The climate of Iceland is cold and subjected to periodic cold spells that exert stress on Icelandic ecosystems, as

do ashfall events during volcanic eruptions. The vegetation of Iceland evolved in the absence of grazing animals. These factors render Icelandic ecosystems particularly sensitive to disturbance and reduced resilience caused by grazing and other land use. Soil erosion in Iceland has remained intense for the past 1200 years since the settlement by Vikings. A unique feature of soil erosion in Iceland is that the full depth of the soil mantle that has formed in eolian and tephra sediments is truncated, leaving barren surfaces (deserts) behind. A survey of erosion in Iceland has been published^[11] showing the great extent and severity of soil erosion in Iceland.

The Icelandic soils are extremely vulnerable to erosion, by both wind and water for many reasons. The formation of stable silt size clusters enhances saltation movement of soil particles, making the soils susceptible to wind erosion. The lack of cohesion while wet and the thixotropic nature of the soils intensify water erosion and landslides. These andic properties that have reduced resistance against erosion are important contributing factors to the severe soil erosion in Iceland.

CONCLUSION

A classification scheme specific to Iceland has been developed, and it has been used to produce a new 1:500,000 soil map.^[11] Icelandic soils are primarily Andosols and Vitrisols according to the Icelandic scheme, which are classified as Andisols according to Soil Taxonomy. The Icelandic soil environment is characterized by cold humid climate and a steady flux of vitric materials to the surface which, together with drainage, are major factors dominating soil formation in Iceland. The extensive Icelandic desert environments are unique considering the humid climate of Iceland. The soils of the deserts are characterized by basaltic vitric materials and are termed Vitrisols.

The andic soil characteristics of the Andisols, such as high water-holding capacity, rapid hydraulic conductivity, thixotropy, and stable silt-sized aggregates, have important implications for intensive cryoturbation and soil erosion in Iceland.

Animals: Ecosystem Functioning

Alan J. Franzluebbers

U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS),
Watkinsville, Georgia, U.S.A.

Abstract

Soil animals are represented by a diverse array of creatures living in or on soil for at least a part of their life cycle. Many animals have influences on soil properties but should not be considered soil dwellers since only a minor portion of their life cycle is spent in the soil. Soil animals can be classified according to body size, where they inhabit the soil, and feeding activity.

INTRODUCTION

Soil animals (i.e., fauna) are represented by a diverse array of creatures living in or on soil for at least a part of their life cycle. Many animals have influences on soil properties but should not be considered soil dwellers since only a minor portion of their life cycle is spent in the soil (Fig. 1).

Based on body size, soil animals can be divided into the following three categories:

1. Microfauna (< 200 μm length and <100 μm width) including protozoa, rotifers, and nematodes
2. Mesofauna (0.2–10 mm length and 0.1–2 mm width) including tardigrades, collembola, and mites
3. Macrofauna (>10 mm length and >2 mm width) including millipedes, spiders, ants, beetles, and earthworms

Soil animals can also be classified according to where they inhabit the soil. The aquatic fauna (e.g., protozoa, rotifers, tardigrades, and some nematodes) live primarily in the water-filled pore spaces and surface water films covering soil particles. Earthworms are divided into species that occupy the surface litter of soil (epigeic), that are found in the upper soil layers (endogeic), or that burrow deep into the soil profile (anecic).

A further classification of five groups of soil animals is based on feeding activity, which can be useful in distinguishing how different groups affect soil ecosystem functions:

1. Carnivores feed on other animals. This group can be subdivided into the following two categories: 1) predators (e.g., centipedes, spiders, ground beetles, scorpions, ants, and some nematodes), who normally engulf and digest their smaller prey and 2) parasites (e.g., some flies, wasps, and nematodes), who feed on or within their typically larger host organism.
2. Phytophages feed on living plant materials, including those that feed on aboveground vegetation (e.g., snails

and butterfly larvae), roots (e.g., some nematodes, fly larvae, beetle larvae, rootworms, and cicadas), and woody materials (e.g., some termites and beetle larvae).

3. Saprophages feed on dead and decaying organic material and include many of the earthworms, enchytraeids, millipedes, dung beetles, and collembola (or spring-tails). They are often referred to as scavengers, debris feeders, or detritivores.
4. Microphytic feeders consume bacteria, fungi, algae, and lichens. Typical microphytic feeders include mites, collembola, ants, termites, nematodes, and protozoa.
5. Miscellaneous feeders are not restrictive in their diet and consume a range of the previously mentioned sources of food. This group includes certain species of nematodes, mites, collembola, and fly larvae.

The arrangement of these feeding groups can be visualized as a soil food web with multiple trophic levels, beginning with the autotrophic flora (Fig. 2). Trophic levels describe the order in the food chain. The first trophic level is composed of photosynthetic organisms, including plants, algae, and cyanobacteria, which fix carbon dioxide (CO_2) from the atmosphere into organic compounds. Organisms that consume the photosynthesizers are in the second trophic level, which includes bacteria, actinomycetes, fungi, root-feeding nematodes and insects, and plant pathogens and parasites. The third trophic level feeds on the second trophic level, including many of the dominant soil animals, including bacterial- and fungal-feeding arthropods, nematodes, and protozoa. The soil food web can be continued to include various vertebrates, including amphibians, reptiles, and mammals.

SPATIAL DISTRIBUTION OF SOIL ANIMALS

Soil animals are not uniformly distributed in soil. Unlike the soil microflora, which could be considered ubiquitous,

Fig. 1 Categories of soil animals defined according to the degree of presence in soil, as illustrated by some insect groups.

Source: From Wallwork.^[1]

the proliferation of soil animal communities is more sensitive to environmental disturbances and ecological interactions. Gross climatic differences afford opportunities for unique assemblages of organisms. Even within a specific climatic region, large differences occur in the community of organisms present based on the type of vegetation, soil, availability of water, land use, and the presence of xenobiotics. Within the confines of a seemingly uniform pedon, “hot spots” of soil organism activity can be isolated based on the localized availability of resources and environmental conditions (Fig. 3).

INFLUENCE OF SOIL ANIMALS ON SOIL FUNCTIONS

Decomposition and Nutrient Cycling

Soil animals work directly and indirectly with the soil microflora (i.e., bacteria, actinomycetes, fungi, and algae) to decompose organic matter and mineralize nutrients.^[3] The primary consumers of organic materials are the soil microflora. Soil animals, like many of the microflora, are heterotrophs and therefore consume organic materials to

gain energy for growth and activity. Soil animals make important contributions to decomposition by:

1. Shredding organic materials, thereby exposing a greater surface area for enhancing the activities of other organisms, especially microorganisms;
2. Consuming resistant plant materials that would decompose slowly otherwise, such as wood, roots, and dung, and transforming these materials into more decomposable constituents;
3. Dispersing soil microorganisms (i.e., inoculation) within the soil profile by transporting them on their bodies and through their intestinal tracts;
4. Creating burrows in soil to increase aeration, which stimulates microbial activity;
5. Transporting organic materials from the soil surface to deeper in the soil profile, thereby improving environmental conditions for decomposition and increasing biological interactions deeper in the soil profile;
6. Consuming bacteria and fungi, thereby releasing nutrients and stimulating the regeneration of microbial populations; and
7. Providing unique food sources themselves for consumption by other soil fauna and microflora.

Fig. 2 Generalized diagram of a soil food web.

Water Cycling

Soil animals are active participants in the formation of soil structure, which is an important characteristic that influences water infiltration, soil water retention, and percolation.^[4] The biochemical activity of soil organisms transforms organic materials into soil-stabilizing cementing agents, which bind the primary soil particles (i.e., sand, silt, and clay) into aggregates. In addition, the burrowing activity of soil animals creates larger pores alongside water-stable aggregates to increase total porosity of soil, which aids water flow without decreasing overall water retention capacity and improves the plant rooting environment.

Both aggregates and porosity are important components of soil structure. Poor soil structure due to disruption of

system. They are able to decompose cellulose in wood because they harbor various microorganisms (protozoa, bacteria, or fungi) to aid in decomposition. Better drainage and aeration of termite mounds may be beneficial to nearby plant growth in soils with a high water table. Stable macro-channels created by termites can improve water infiltration into soils that otherwise would form impermeable surface crusts.

Protozoa

Protozoa are single-celled animals that generally consume bacteria and soluble organic matter. They are more numerous in marine and freshwater environments but do occur widely in water films of many soils.^[5] Their principal soil function is predation on soil bacteria, which releases nutrients for potential plant uptake; increases decomposition and soil aggregation by stimulating their bacterial prey; and prevents some bacterial pathogens from developing on plant roots.

SOIL BIODIVERSITY

There has been a great deal discovered about soils and the organisms that live in them, yet it is estimated that <10% of the species of soil organisms have been identified globally. A rich diversity of genetic information resides in soil. An awaiting challenge is to discover the ecological consequences of soil biodiversity. A critical understanding of how organisms interact has begun, yet there will be much more to learn about how species diversity interacts with functional diversity. There may be soil functions provided by organisms that we are unaware of.

How biodiversity relates to ecosystem functioning is an intensive area of modern research in both aboveground and belowground ecology.^[6,7] The experimental evidence

suggests that the loss of species richness due to perturbations may not always lead to the loss of ecosystem functioning, especially in initially species diverse functional groups.^[8] Ecosystem functions can be performed by a number of different species within a trophic level, suggesting that functional redundancy is a mechanism to insure stability. However, the loss of functional groups in trophic levels closest to the base of the detrital food web would be the most detrimental to ecosystem stability. Future work on soil biodiversity should unravel the relative importance of species richness on the resistance and resilience of ecological processes under various short- and long-term stresses and environmental conditions.

Animals: Microbial Interactions and Nutrient Cycling

Lisa Cole

Richard D. Bardgett

Department of Biological Sciences, Institute of Environmental and Natural Sciences,
University of Lancaster, Lancaster, U.K.

Abstract

Although most mineralization of nutrients is governed directly by the activities of bacteria and fungi, their ability to do this is strongly affected by soil animals. The effects of biotic interactions on the structure and activity of microbial communities, and the consequences of this regards nutrient mineralization, are discussed for the common groups of macro- and mesobiota found in soils, namely the earthworms, microarthropods, and enchytraeid worms.

INTRODUCTION

The decomposer food web has a primary role in determining the mineralization of nutrients in soil and hence plant nutrient acquisition and plant productivity.^[1] Although most mineralization of nutrients is governed directly by the activities of bacteria and fungi, their ability to do this is strongly affected by soil animals. Soil animals affect microbial communities either directly through selectively feeding on fungi and bacteria or indirectly by comminution of organic matter, dissemination of microbial propagules, and the alteration of nutrient availability.^[2] Combined, these interactions between microorganisms and animals drive the ecosystem-level processes of energy flow and nutrient cycling and, therefore, contribute to primary production.^[3–5] The effects of these biotic interactions on the structure and activity of microbial communities, and the consequences of this regards nutrient mineralization, will be discussed for the common groups of macro- and mesobiota found in soils, namely the earthworms, microarthropods, and enchytraeid worms.

SELECTIVE FEEDING BY SOIL FAUNA

Although soil animals are considered to be both generalist and opportunist in their feeding behavior, two main groups of feeder that have been distinguished are bacterivorous and fungivorous. The structure of the microbial community is to some extent controlled by the selective feeding activities of these animal groups; selection of prey is based on their palatability, which varies with species, age, and physiological status; e.g., the collembolan *Folsomia candida* has been shown to feed on metabolically active hyphae in preference to dead or inactive hyphae^[6] and also selects regions of the fungal thallus with high

nitrogen (N) content.^[7] Preferential grazing is also thought to arise as a result of the avoidance of toxins that are produced by some fungal colonies,^[8] and some species of Collembola have been shown to locate and select their fungal food source by volatile compounds released from fungal mycelium.^[9]

Intermediate levels of grazing have been shown to enhance the activity and growth of selected fungi.^[10] Stimulation of fungal growth, which is often referred to as compensatory growth, is due to new fungal growth after senescent hyphae are grazed and regrowth after periodic grazing of actively growing mycelia. For example, grazing of the fungus *Mortierella isabellina* by the collembolan *Onychiurus armatus* induced switching from a “normal” hyphal mode, with appressed growth and sporulating hyphae, to fan-shaped sectors of fast-growing and non-sporulating mycelium with extensive areas of aerial hyphae.^[11] In addition, activities of specific amylase (starch-degrading enzymes) were several times higher in grazed cultures than in those cultures that were ungrazed.^[11] Heavy grazing of fungal communities can reduce their activity. For example, heavy grazing of mycorrhizae has been shown to counteract the mutualistic relationship between mycorrhizae and their host plant.^[12]

Selective grazing by soil fauna can alter the composition of the soil microbial community by altering the competitive relationships between species of microorganisms. Selective grazing by the collembolan *Orthogonius latus* on the fungus *Marasmius androsaceus* in coniferous leaf litter resulted in a reduction in the activity of this palatable fungi and an increase in an unpalatable fungus *Mycena galopus* present in the litter.^[13,14] Because *M. galopus* decomposes litter at a slower rate than *M. androsaceus*, the presence of *O. latus* reduced the decomposition of leaf litter.^[13,14]

The ingestion and exposure of microbes to intestinal fluids can influence microbial activity. Microbial

communities have been shown to be more abundant and active following passage through the gut of earthworms.^[15] The passage of microorganisms through earthworm (e.g., *Lumbricus terrestris*) guts has been shown to activate dormant bacteria due to the removal of endospore cell coats and subsequent germination of bacterial spores.^[16] Conversely, it has been suggested that the earthworm gut is a hostile environment for soil fungi;^[17] the germination of fungal spores (*Fusarium lateritium*, *Agrocybe temulenta*, *Trichoderma* sp., and *Mucor hiemalis*) was reduced following ingestion by *L. terrestris* and *Aporrectodea longa*. It was demonstrated that the germination of fungal spores was enhanced by physical abrasion by soil particles in the gut, but that subsequent exposure to intestinal fluid significantly reduced germination.^[17]

EFFECTS ON NUTRIENT CYCLING AND PLANT GROWTH

The most studied interactions between invertebrates and the microbial community in soils involve those that result in the release of nutrients from the microbial biomass as a result of the feeding activities (grazing) of animals. In general, soil fauna have lower carbon (C)/N ratios than the microbes upon which they graze, and therefore they excrete nutrients that are not required for production in forms that are biologically available (i.e., inorganic forms—"mineralized"). This release of nutrients into the soil system is effectively remobilization of the nutrients that were bound up in the microbial biomass and has been termed the "microbial loop."^[18] In addition, this grazing of microorganisms often leads to changes in the structure, size, and activity of the microbial community in the soil; as discussed above, these changes in microbial communities indirectly affect the processes of nutrient mineralization.

Many studies demonstrate the positive effects of soil fauna on C turnover and N mineralization in soil and litter materials. A study that used litter bags buried in the field^[19] demonstrated that the exclusion of enchytraeids and dip-teran larva from the litter bags resulted in lower rates of decomposition of litter. Likewise, laboratory microcosm studies have shown that the presence of different groups of animals in soil enhances the processes of nutrient mineralization; e.g., the grazing activities of enchytraeids on microorganisms that colonize litter have been shown to result in increased rates of leaching of ammonium and dissolved organic C^[20,21] associated with increased microbial activity.^[21] The earthworm *Aporrectodea caliginosa* has been shown to increase C and N mineralization in soils amended with birch litter,^[22] despite a reduction in the microbial biomass. The grazing of fungi on litter by the Collembola *F. candida*^[23] and *Tomocerus minor*^[24] also increased the mineralization of N. These positive effects of soil fauna have been shown to translate into increased uptake of nutrients and growth of plants. It has been shown

that Collembola and nematodes increased the concentrations of ammonium in the soil solution of an upland organic soil, leading to increased plant nutrient uptake by an upland grass species, *Nardus stricta*.^[4] It has also been demonstrated that although grazing by the earthworm *A. caliginosa* reduced the root biomass of the grass *Hordelymus europaeus*, this was associated with an increased N content in its shoot and roots, due to increased availability of mineral N in the presence of the earthworm.^[5] The leaf, stem, and shoot biomass of birch seedlings (*Betula pendula*) was increased when grown in the presence of a diverse soil fauna.^[3] Further studies have demonstrated that reductions in microbial biomass through grazing activities of soil fauna can benefit plant growth, most likely as a result of increased activity of the microorganisms. For example, grazing of ectomycorrhizal fungi associated with *B. pendula* by a diverse soil fauna resulted in enhanced growth of and nutrient uptake by *B. pendula*, despite reductions in the biomass of ectomycorrhiza.^[25]

The effects of interactions between fauna and microorganisms on nutrient release are often regulated by resource quality. In studies of N-limited soil, Collembola did not increase the amount of nitrate and ammonium released into soil solution, because the extra N that was released as a result of animal grazing was rapidly re-utilized by the growing fungus that was nutrient limited.^[10] Similarly, a microcosm study showed that collembolan grazing on a leaf litter-inhabiting fungus had no effect on nutrient release due to efficient re-utilization of nutrients by the fungus.^[26] These studies, however, were conducted in the absence of plants, which are effective competitors with microbes for nutrients in N-limited soil.^[27] Studies of ecosystem-scale N cycling point to the importance of these animal-microbial interactions in controlling seasonal patterns of plant-microbial competition for nutrients in nutrient-limited ecosystems.^[27]

Some works suggest that the effects of these biotic interactions on nutrient release are complex and involve a diversity of species in more than one trophic group;^[28,29] e.g., the effects of feeding of fungal-feeding Collembola on nutrient cycling have been shown to become apparent only when they are interacting with another trophic group of soil fauna, namely microbial-feeding nematodes.^[4] Likewise, it has been demonstrated that combinations of soil animals, as opposed to a single group of soil fauna, had a synergistic effect on the microbial community in microcosms of coniferous forest humus, resulting in enhanced leaching of mineral nutrients.^[30] There is also evidence for top-down regulation of microbial biomass and nutrient mineralization rates in studies with microbes, microbivorous nematodes, and predatory organisms.^[31] However, some microcosm studies^[32] show that lower trophic levels in soil food webs are considerably more important than higher ones in regulating ecosystem productivity, as measured by plant growth. What is clear from these studies is that further testing of the effects of soil fauna on plant-microbe nutrient

competition needs to examine the influence of more complex trophic relations.

Although not a direct interaction, the ability of soil fauna to comminute or fragment organic materials indirectly influences the activity of microorganisms that are involved in decomposition and nutrient cycling by increasing the surface area available for microbial colonization.^[19,33]

DISPERSAL OF MATERIALS

The movement of animals through the soil provides a passive means of transport for microbial propagules to new sites in the soil, both through the attachment and transport of microbes on the body surface and through the ingestion and excretion of microbes at new sites in the soil. Mites, Collembola, and earthworms have been shown to carry propagules of several species of saprotrophic fungi and arbuscular mycorrhizal fungi.^[34,35] Soil fauna also transport plant pathogens; the earthworm *L. terrestris* is known to enhance the dispersal of *Syntrichium endobioticum*, the causal agent of wart disease of potato.^[36] This has led to concerns that soil fauna may provide a means for the dispersal of genetically modified organisms. The beneficial role of soil fauna for the delivery of biocontrol agents to the rhizosphere is also a research theme in the control of root pathogens.

Abstract

Antimony (Sb), a non-essential, toxic metalloid, is classified as a pollutant of priority interest by the U.S. Environmental Protection Agency. In soils, Sb is commonly oxidized to pentavalent antimonate, $\text{Sb}(\text{OH})_6^-$. Iron and manganese oxides are important sorbents, but $\text{Sb}(\text{OH})_6^-$ is relatively mobile in neutral and alkaline soils. In reducing conditions, Sb may form $\text{Sb}(\text{OH})_3$ or Sb sulfides. $\text{Sb}(\text{OH})_3$ is sorbed to oxides over a wide pH range. Due to the increased industrial use of Sb, contamination of the soil is of growing concern. In the most contaminated soils, the negative effects of Sb on plant growth and nitrification may be expected.

INTRODUCTION

The natural sulfide of antimony (Sb) was known and used in biblical times as medicine and cosmetic. Pliny (A.D. 50) referred to the metal as stibium, from which the chemical symbol Sb is derived. The name antimony is attributed to the Greek words *anti* and *monos*, which means “enemy of solitude” or “metal not found alone.”^[1] Sb is toxic and classified as a pollutant of priority interest by the U.S. Environmental Protection Agency.^[2] Due to the increased industrial use of Sb, contamination of the soil is of growing concern. Here, we discuss the most important aspects of Sb contamination of soils, including its sources, geochemistry, common concentration ranges, and toxicity.

CHEMISTRY OF Sb

Sb, a metalloid in group 15 of the periodic table, exists in a variety of oxidation states (−III, 0, III, V), with oxidation states III and V being the most common in the natural environment. In the lithosphere, Sb occurs as Sb sulfides, metal antimonides, and antimonoxides. The principal Sb-containing ore minerals are stibnite (Sb_2S_3) and valentinite [antimony trioxide (Sb_2O_3)].^[1] The physical and chemical properties of Sb are given in Table 1.^[1,3]

The predominant inorganic Sb species in soils are Sb(III) [as $\text{Sb}(\text{OH})_3^0$] and Sb(V) [as $\text{Sb}(\text{OH})_6^-$]. These species behave differently; thus, the redox state is important for the fate of Sb in the environment (Fig. 1). Sb is present as soluble $\text{Sb}(\text{OH})_6^-$ in oxic systems and as soluble $\text{Sb}(\text{OH})_3^0$ in more reduced systems. In reducing conditions, $\text{Sb}_2\text{S}_3(\text{s})$ may form at low pH. Inorganic species of Sb predominate over organic species in the most environment systems.^[5]

ABUNDANCE AND SOURCES OF Sb IN SOIL

In 2009, Sb was the ninth most exploited metal worldwide with approximately 187,000 tons being mined.^[6] World reserves of Sb are estimated to be in excess of two million tons and are located principally in Bolivia, China, Russia, South Africa, and Mexico. Sb is primarily used as a hardener in lead (Pb) for storage batteries but also in solders and other alloys (e.g., used in bullets). Sb_2O_3 , the most important industrially used Sb compound, is primarily used in flame retardants but also in paint pigments, glass, and ceramics. Organoantimony compounds are commonly used to treat tropical protozoan diseases (e.g., leishmaniasis).^[7]

Sb compounds are increasingly released into the environment during incineration of waste, combustion of fossil fuels, e.g., coal and petroleum, and smelting of metal ore. Other sources of Sb contamination of soils include ammunition at shooting ranges, road traffic (dust from brake linings and tires), and older battery-producing plants.^[8] Background concentrations of Sb in unpolluted soils (Table 2) are low (a few milligrams per kilogram). Higher concentrations are generally related to anthropogenic sources. Filella et al. have carried out an extensive literature review of the occurrence of Sb in the environment.^[8,9,10]

MOBILITY OF Sb IN SOIL

The fate and mobility of Sb in soil depend on speciation, soil characteristics, and environmental conditions. In soil, Sb is commonly oxidized to Sb(V), which is the dominant form observed in contaminated soils near smelters and at shooting ranges.^[11,12] Oxidation is enhanced by iron (Fe) and manganese (Mn) oxides.^[5,13,14] For example, in soil

Table 1 Physical and chemical properties of Sb.

Property	Value
General	
Atomic number	51
Periodic table group	15
Group name	Pnictogen
Electronic configuration	
Ground state electron configuration	[Kr].4d ¹⁰ .5s ² .5p ³
Shell structure	2.8.18.18.5
Atomic mass (relative to ¹² C = 12.0000)	121.75
Naturally occurring isotopes	¹²¹ Sb (57.21%) ¹²³ Sb (42.79%)
Ionization energies (kJ/mol)	
M → M ⁺	833.7
M ⁺ → M ²⁺	1794

water 5 m downward the mine pit at the closed-down Ichinokawa Sb mine in Japan, Mitsunobu et al.^[12] found Sb to be in the oxidized form. In contrast, even at 1 cm depth, arsenic (As) mainly occurred in the reduced state (Fig. 2^[12]).

Due to its anionic character, Sb(V) is relatively mobile in the environment, having a low affinity for clay minerals.^[8] Natural Fe and Mn oxides are the most important sorbents in soil.^[5] The strongest sorption of Sb(V) in soil occurs at pH < 6 (Fig. 3^[13]). At pH > 6, the sorption of Sb shows a strong decreasing trend and is small compared with that of As and phosphorus (P). In contrast, the neutral Sb(III) is strongly sorbed to Fe oxides over a wide pH range of 3–12. The role of Sb interaction with organic phases is largely unexplored.^[5]

The sorption of Sb, commonly expressed by the distribution coefficient (K_d), depends on soil properties. Values reported in the literature vary greatly. For example, in agricultural soils in Japan, K_d values ranged from 1 to

**Fig. 1** Eh–pH diagram for the soluble Sb species at 25°C and a Sb concentration of 10^{−8} mol/L.

Source: From *The Geochemist's Workbench*.^[4]

2065 L/kg, with a mean of 62 L/kg. K_d values increased with decreasing pH and decreased with increasing phosphate concentration.^[15] For soils (down to 60 cm) at shooting ranges, K_d values varying between 158 L/kg and 2512 L/kg were found.^[16] At high contamination levels, precipitation of Ca-antimonate may control the concentrations of Sb(V) in soil water.^[10]

Table 2 Some published Sb concentrations in soils.

Soils	Total Sb (mg/kg dry weight)
Unpolluted soil, B horizon, the United States (1000 samples)	<1–8.8
Market-garden soils, marsh (surface soil), the Netherlands	1.85–2.11
Soil, Scotland, the United Kingdom (10 samples)	0.29–1.3
Humus layer of Norwegian soils (10 regions)	0.17–2.20
Sandstone and sands, Zimbabwe (arsenical soils)	50–5000
Soil near stack at gold-refining site, Yellowknife, Northwest Territories, Canada	280
Soils close to a Pb smelting complex (0.4–19 km from smelter, top layer), Kellogg, Idaho, the United States	5–260
Soils close to six different Copper smelter sites, the United States	3–204
Soils in proximity to Sb smelter (100 m from smelter), River Tyne, the United Kingdom	170–360

Fig. 2 Depth profile of Sb(III) and Sb(V) concentrations in soil water downward the mine pit at Ichinokawa mine, Japan.

Source: Reprinted in part with permission from Mitsunobu, Harada, et al.^[12]

Biologically mediated methylation of Sb, e.g., to monomethylstibine (CH_3SbH_2), has been detected in soils and plants. In urban soil samples from the German Ruhr basin, the highest concentrations of methylated Sb were observed in agricultural and garden soils, due to cultivation and a high biological activity (up to 1.6% of the total Sb content).^[17] Methylated Sb concentrations in the environment are low and are not considered to be of great concern.^[8]

TOXICITY AND BIOLOGICAL EFFECTS

Sb, a non-essential element, is toxic at high concentrations. The toxicity is a function of water solubility and oxidation state, and in general, Sb(III) is more toxic than Sb(V).^[8] The World Health Organization drinking water limit for Sb is set at 20 $\mu\text{g/L}$.^[18]

Fig. 3 Sorption of Sb(V) on goethite at $I = 0.01 \text{ M}$ (solid symbols) and $I = 0.1 \text{ M}$ (open symbols). Experimental conditions: $[\text{Sb(V)}]_0 = 4.15 \mu\text{M}$, 0.5 g/L goethite, 25°C. Dashed lines show predicted adsorbed P and As concentrations for the same initial concentrations of anions and goethite.

Source: Reprinted in part with permission from Leuz, Monch, et al.^[13]

The knowledge about the toxicity of Sb in soils is limited. In laboratory toxicity tests, half maximal effective concentration values for Sb range from 70 to >1000 mg/kg.^[19,20] Reported values depend on end point, soil, and the Sb form tested. Thresholds for the toxicity of Sb (V) with respect to plant growth and nitrification were over 100-fold larger than background concentrations in the European soil (0.1–1.9 mg/kg, Table 2).^[14]

It is not clear whether bioaccumulation of Sb occurs.^[9] In Sb-mining areas, high Sb concentrations have been found in vegetation (up to 1400 mg/kg).^[21] Furthermore, studies on invertebrates and mammals from grassland in the vicinity of a Sb smelter showed elevated Sb concentrations in tissues. On the other hand, other studies in such Sb-contaminated areas have shown low uptake and bioaccumulation in plants and microorganisms, due to low solubility of Sb in water. Similarly, plants growing in contaminated soils (concentrations up to 500 mg/kg) have about the same level of Sb uptake as plants growing in uncontaminated soils.^[16]

CONCLUSION

Sb occurs at increasing concentrations in soils, due to its growing industrial use. In oxic conditions, Sb occurs mainly as Sb(V) $[\text{Sb(OH)}_6^-]$. Fe and Mn oxides are the most important sorbents for Sb(V), particularly in acidic soils. In neutral and alkaline soils, Sb(V) is relatively mobile. Sb(III), important in reducing conditions, is sorbed strongly to oxides. Due to its increased use, elevated concentrations in the environment, and toxicity, further research on Sb is warranted.

Ants

Walter G. Whitford

Jornada Experimental Range, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Las Cruces, New Mexico, U.S.A.

Abstract

Ants contribute to heterogeneity in soil properties by the construction of subterranean nests and by accumulating organic materials in and around nests. The construction and maintenance of nests affect soil turnover, macroporosity, and mixing of soil profiles. Foraging and food processing behaviors affect soil nutrient concentrations and soil microflora and microfauna. The magnitude of the effects of ants on soils is dependent upon soil type and topographic position.

INTRODUCTION

Ants are among the most ubiquitous insects on the planet. They inhabit in all biomes except for the extreme polar regions. In the biomes where ants are abundant, they affect many soil processes that contribute to the creation of patch mosaics that characterize the soils and vegetation of many landscapes. The abundance and diversity of soil-nesting ants vary from as high as 7000 colonies per hectare in tropical savanna to as few as 3–4 colonies per hectare on some periodically flooded, fine-textured soil, desert landscape units.^[1] Soil-nesting ants affect critical ecosystem processes such as nutrient cycling and water redistribution. Ant nest mounds vary from a few centimeters in height and diameter to >1 m in height and >2 m diameter.^[2] Ant nests consist of underground and branched networks of galleries and chambers. Surficial chambers are connected to lower chambers by vertical galleries with branching lateral galleries. Galleries and chambers vary in size and number, depending upon the species of ant. For example, *Lasius neoniger*, an abundant ant species in temperate North America, constructs tubular galleries of 1.5–5.0 mm diameter and chambers of 10–20 mm diameter and 30–50 mm length. The volume of *L. neoniger* nests ranges from 20 to 250 cm³ and the nests are confined to the upper 70 cm of soil.^[3] Other species construct nests to depths ranging from 50 cm to greater than several meters, depending upon species-specific behavior, soil type, and landscape position. Soil profile mixing, texture, physical and chemical property modification of mound soils, soil macroporosity, and geomorphological attributes of ant nest mounds vary with species-specific colony longevity, body size, and numbers of workers of a colony, soil type, and landscape position. The perturbation effects of ants therefore depend upon the species composition of the ant community, geomorphic history, soil properties, and topographic position of a landscape unit.

Because most studies concerning the effects of ants on soils have focused on one or two species, a comprehensive analysis of the combined effects of all ant species on the soils of an ecosystem cannot be made.

MICROTOPOGRAPHY

In areas that are periodically flooded or where the water table is close to the surface, some species of soil-nesting ants build mounds that create favorable microhabitats for themselves and also a habitat for some species of plants that are confined to the aerated soils of the ant mounds. Soil-nesting ants create hummock microtopography in some wet meadow fens and tropical wet savannas.^[4] In the Chaco region of South America (parts of Paraguay, Bolivia, Argentina, and Brazil), nest mounds of *Campotonotus punctulatus* occur at densities of between 200 and 1000 mounds/ha. These conical mounds average a height of 0.62 m (with a maximum of 1.85 m) with a mean basal diameter of 1.2 m. The mound soils are lighter textured than surrounding soils, reflecting the amount of materials transported from surrounding subsurface soil during mound construction.^[5] *Formica podzolica* mounds in a Montana fen are thought to contribute to the hummock-hollow microtopography of peat lands. Abandoned *F. podzolica* mounds provide drier and warmer microsites that are enriched with some soil nutrients.^[4] The mounds of *Lasius flavus* contribute to the microtopography of some European grasslands and salt marshes.^[6] Mima-type earth mounds up to a height of 1.5 m with a diameter of 20 m in Buenos Aires Province, Argentina, are produced by horizontal translocation of soil to the colony sites of black fire ants, *Solenopsis richteri*. Continued occupation of the mounds by successive generations of ants gradually increases the size of the mounds to mima-type size.^[7] Ants (*Formica* spp. and *Myrmica* spp.) are

important agents in the process of development and maintenance of hummock microtopography of subarctic peatlands. Hummock retrogression is accelerated by the tunneling activity of ants.^[8]

HETEROGENEITY OF PHYSICAL AND CHEMICAL PROPERTIES OF THE SOIL

Many species of ants alter the texture and chemistry of the soil in the nest mounds. The nutrients most frequently reported to be at higher concentrations in ant mound soils include nitrogen, phosphorus, potassium, calcium, magnesium, manganese, and iron.^[9] The effect of soil-nesting ants on soil nutrient patchiness and on vegetation varies as a function of landscape position, soil type, and the biology of the ant species. Nutrient enrichment of mound soils has been reported for several species of seed-harvesting ants and omnivorous species of ants that collect seeds, prey on insects, or collect insect carrion. Species of soil-nesting ants that enrich the nutrient content of mound soils are characterized by relatively long-lived colonies (>5 years) and the behavior of depositing chaff and unwanted insect parts on and around the nest mound or disk. Nutrient enrichment of mound soils by a species may not occur on all soils on a watershed or landscape. For example, *Pogonomyrmex rugosus* nest disks in desert shrubland and mixed shrub grassland were nutrient enriched, but the nest disks of this species in a piedmont grassland were not nutrient enriched.^[10] *Formica* spp. mounds in forest were nutrient enriched, but *Formica* spp. mounds in meadows and grasslands were not.^[11]

The variability in soil nutrient enrichment of ant mounds has been documented in several species of leaf-cutting ants. In remnant Cerrado (woodland savanna), Brazil, leaf-cutting ants (*Atta* spp.) had no detectable effect on nutrient enrichment.^[12] In northern Patagonia, soils associated with the leaf-cutting ant, *Acromyrmex lobicornis*, had higher concentrations of nitrogen, phosphorus, and organic matter than reference soils.^[13] The location of nutrient-rich organic refuse produced by leaf-cutting ant colonies varies among species. *Atta cephalotes* deposit organic refuse in subterranean chambers, whereas *Atta colombica* place organic refuse on the soil surface near the nest. The location of organic refuse is a major factor affecting nutrient concentrations and the composition, abundance, and activity of soil microflora and microfauna.^[14] In the Orinoco Llanos savanna, Venezuela, *Atta laevigata* nests had higher concentrations of nitrogen, magnesium, calcium, and organic carbon, but other soil nutrients and properties were not affected by ant mounds.^[15]

In an Australia Vertisol, ant nest soils had greater concentration of coarse and particulate organic matter, lower fine particulate soil organic matter (SOM)/coarse

particulate SOM ratios, larger sand content, and lower clay content than surrounding soils.^[16] Nutrient enrichment of nest mound soils of funnel ants (*Aphaenogaster barbigula*) was attributed to entrapment of organic materials around the nest entrances. Reexcavation of nest chambers after rainfall buries trapped litter, resulting in higher concentrations of nitrogen, organic matter, and some cations compared to nest-free soils.^[17] In humid tropical savanna, ant mounds of *Camponotus* spp. had higher clay and coarse sand content than surrounding soils.^[9] Even exotic or alien species of ants change the chemical and physical properties of nest mound soils. Mounds of imported fire ants (*Solenopsis invicta*) had higher concentrations of clay, phosphorus, and potassium and lower concentration of SOM than reference soils. The effect of *S. invicta* on calcium concentrations relative to reference soils was dependent upon the characteristics of the unmodified soil.^[18]

Ants change the nutrient concentration of mound soils, but the physical and chemical properties of mound soils can also affect mineralization processes. Nitrogen mineralization rates were reduced in nest mound soils in moss sedge, sedge, and alder peat habitats.^[19]

SOIL TURNOVER

The longevity and turnover rates of nests and nest mounds of ants in a community frequently follow a distribution gradient from high turnover (<3 months) to long-lived (>10 years). The importance of ants in the transport of subsurface horizon materials to the surface varies with the density and diversity of the ant community on a landscape unit. In Chihuahuan Desert grasslands, soil-nesting ants are an order of magnitude more abundant on sand and sandy loam soils than on fine-textured soils. Ants were estimated to move between 21.3 and 85.8 kg/ha/yr on sandy and sandy loam soils and between 0.1 and 3.4 kg/ha/yr on clay and clay-loam soils.^[20] The estimated annual soil turnover by ants in an *Atriplex vesicaria* shrubland in the semiarid region of Australia was 350–420 kg/ha/yr.^[9] Soil that is excavated by ants in the construction of galleries and chambers and deposited on mounds around nest entrances is generally eroded by water and wind within a year unless the mound is protected from raindrop splash erosion by gravel, stones, or wood fragments. Nest mound soils may be replenished by the belowground expansion of galleries and chambers. Ant nest mounds in sparsely vegetated arid regions are prone to wind erosion. On an Australian Aeolian soil, funnel ants' (*A. barbigula*) nests were active for approximately 9 months and the ants changed location approximately twice per year. Soil transport was estimated to be 33.6 kg/ha, and it was estimated that 92% of the soil volume would be turned over by these ants in 100 years.^[21] In Western Australia, ant communities on gray soils of semiarid woodlands were

estimated to turnover 46.5 kg ha/yr and on yellow soils, the soil-nesting ant community was estimated to turnover 22.3 kg/ha/yr.^[22] In a humid savanna environment, one abundant ant species, *Paltothyreus tarsatus*, was estimated to transport approximately 30 g/m²/yr of sand particles and soil aggregates. This ant species increased the concentrations of clay, carbon, iron oxides, and coarse sand in the A horizon.^[9] The amount of soil transported to the surface by *Pogonomyrmex occidentalis* in pinon-juniper woodland and ponderosa pine forest was estimated to be 650 kg/ha.^[23] Soil turnover by the ant community in New England forest soil was estimated to be over 50 kg/ha/yr. It was concluded that the translocation of B-horizon materials to the soil surface by soil-nesting ants was an important process in podzol formation in New England forest soils.^[24]

Some long-lived species of soil-nesting ants relocate their nests one or more times a year. The construction of new nests results in the transport of a volume of soil equal to the volume of galleries and chambers to the soil surface. Most of that soil originates in lower soil horizons and contributes to soil profile homogenization. The relocation of nests by some species of ants results in lower estimates of soil turnover than occurs in some environments.

SOIL WATER RELATIONS

The structure of nests of soil-nesting ants provides extensive macroporosity to the soil in which the nests are constructed. The macropores constructed by ants affect rates of infiltration and rates of percolation. In some environments, extremely high densities of nest entrances can have a dramatic effect on infiltration. In semiarid Western Australia, ant biopores were found to transmit water down the soil profile only when the soil was saturated and water was ponding on the surface.^[25] On Aeolian sand soils in Australian semiarid woodland, densities of nest entrances of funnel ants (*A. barbigula*) were estimated at 88,000 per hectare. Steady-state water infiltration on soils with nest entrances averaged 23.3 mm/min, in comparison to an infiltration rate of 5.9 mm/min on nest-entrance-free soil.^[26] In semiarid woodland of Eastern Australia on red earth soil, ponded steady-state infiltration averaged 1026 mm/hr on soil with nest entrances of *A. barbigula*, but only 120 mm/hr on soils without nest entrances.^[27] Bulk flow along nest galleries provides an important route of recharge of deep soil moisture in arid and semiarid environments.

Ant gallery macropores are not always avenues for bulk flow. In a study of a mesic Typic Quartzipsamment, there was no preferential flow down ant galleries. The lack of an effect on hydraulic conductivity was attributed to the sandy soil.^[28] In another study of a sandy soil, the estimated saturated soil matrix hydraulic conductivity of nest

burrows was approximately eight times smaller than that of the bulk sandy soil. This reduction in hydraulic conductivity was attributed to the ants' in-filling of gallery walls with fine materials.^[28]

EFFECTS ON OTHER SOIL BIOTA

Soil around relatively long-lived ant colonies may be enriched with microflora, microfauna, and mesofauna. The soils of nest disks of western harvester ants, *P. occidentalis*, are enriched with vesicular-arbuscular mycorrhizal fungi.^[29] In areas of North America dominated by the red imported fire ant, *S. invicta*, the species composition and abundance of soil yeast within mounds are altered by changes in soil properties produced by fire ants.^[30] Mound soils of *Formica aquilonia* are dominated by bacteria-feeding microfauna and have a higher microbial biomass than the surrounding soils.^[31] Species-specific differences in the effect of ants on soil microflora of mounds are related to the feeding strategies of the species and nest architecture. Three ant species, *Myrmica scabrinodis*, *Lasius niger*, and *L. flavus*, differ greatly in foraging strategies and methods of mound construction. Microbial functional diversity and evenness were higher in mound soils of *M. scabrinodis* and *L. niger* than in reference soils but were not different from reference soils in the mounds of *L. flavus*. Different functional groups of microorganisms were activated in the mounds of the different species. Carbon mineralization was higher in mound soils of all three species.^[32]

CONCLUSION

Ants contribute to heterogeneity in soil properties by the construction of subterranean nests and by accumulating organic materials in and around nests. The construction and maintenance of nests affect soil turnover, macroporosity, and mixing of soil profiles. Foraging and food processing behaviors affect soil nutrient concentrations and soil microflora and microfauna. The magnitude of the effects of ants on soils is dependent upon soil type and topographic position.

Archaeology

John E. Foss

University of Tennessee, Knoxville, Tennessee, U.S.A.

Abstract

Pedologists have grown increasingly interested in work on archaeological sites. Although we aid archaeologists in understanding the soils and pedologic features they carefully excavate, we have learned a great deal about weathering rates, horizon formation, and landscape development by teamwork with archaeologists and geologists.

INTRODUCTION

Geology has had a long period of interaction with archaeology, but the use of soil investigation in archaeology has a rather short history. In 1942, Nikiforoff^[1] used the term *archeopedology* for those soil scientists working with fossil soils or Paleosols. Early studies of soils at archaeological sites were concerned mainly with soil chemical properties.^[2–4] An early book by Cromwall^[5] also played an important role in demonstrating the usefulness of soil–archaeological interactions. The past has seen a substantial increase in the multidisciplinary effort between these two sciences and have involved more subdisciplines of soil science.

ROLE OF SOIL SCIENCE IN ARCHAEOLOGY

As archaeologists become more interested in a complete understanding of the chronology and environmental history of sites, a multidisciplinary effort is absolutely necessary. Team members commonly include scientists from soil science, geology, botany, zoology, palynology, and other specializations. Soil science, especially the pedology area (i.e., the study of soil formation and classification), has been particularly active in evaluation of archaeological sites. Pedology, geology, and other earth sciences often work in the specialized field of geoarchaeology, which means using earth science principles to study archaeological sites. Fig. 1 shows a landscape of Tikal, Guatemala (Mayan site); this site is one of the many important archaeological sites that has required the expertise of pedologists to help interpret chronology and land use.^[6–9]

The study of soils and landscapes is an integral part of many archaeological investigations. Some federal and state regulations that require geologic and soil input on archaeological sites have also been responsible for including earth scientists in these studies. Publications in the 20th century indicated the interest of pedologists, geologists, and archaeologists in evaluating soils and landscapes as part of overall archaeological investigations.

Publications such as *Soils in Archaeology* edited by V.T. Holliday,^[8] *Soil Science and Archaeology* by Scudder, Foss, and Collins,^[9] Soil Science Society of America Special Pub. No. 44 on *Pedological Perspectives in Archaeological Research*,^[10] and articles in the *Proceedings of Conferences on Pedo-Archaeology*^[11,12] have raised pedologists' and archaeologists' awareness of the potential contributions of soil studies to site evaluation. The periodical *Geoarchaeology: An International Journal* has also been valuable in promoting earth science activity in archaeological investigations.

Some of the major pedologic contributions to field archaeology have included the following.^[13]

1. Determining site delimitation
2. General pedologic stratigraphy
3. Soil–landscape relationships
4. Identification of geologic parent material
5. Correlating soil morphology and archaeological levels
6. Identifying lithologic (parent material) and pedologic (soil weathering) discontinuities
7. Approximating soil age
8. Identifying Paleosols (fossil soils)
9. Contributing to the overall interpretation of site

In the 20th century, many of the above pedologic contributions to archaeology were made during the final phase of archaeological field work. Pedologists have been more involved in phase 1 activity of archaeological investigations. The early identification of major stratigraphic zones, preliminary analysis of landscape and soil age, and model of site development have resulted in more efficient archaeological excavations and interpretations.

FIELD STUDIES

Archaeological sites occur in many different geologic provinces and landscape positions. Determination of the site context is thus the most important initial stage in pedoarchaeology. Geologic maps can provide general knowledge of a region, but detailed soil surveys provide the most useful introduction to a study area. These maps produced by the

Fig. 1 Landscape view of Mayan city of Tikal, Guatemala.

National Resource Conservation Service, in cooperation with the Land Grant Institutions, are usually on a county-wide basis using an air photo base with a scale of 1:15,840–1:24,000. At this scale, there is not sufficient detail to relate the morphology of individual soil mapping units to specific horizons encountered at an archaeological site. The landscape and physiographic position of each soil mapping unit, however, are useful in preliminary analysis of archaeological sites.

The most important and informative archaeological sites occur in landscapes where sediment is added to a pre-existing surface, thereby protecting the artifacts and soil horizons. Those buried sites may occur in the following areas or situations:

1. Alluvial deposition
2. Volcanic activity
3. Eolian deposition
4. Colluvial slopes
5. Mass movement or slumping
6. Seismic areas
7. Artificial deposition or destruction

These situations provide the opportunity for soil burial (subsequently termed Paleosols) and archaeological levels. The buried surfaces (A horizons) of these Paleosols are particularly good sources of artifacts and living surfaces, when the events above took place in the Holocene. Holliday^[8] provides an excellent background in the use of paleopedology in archaeology.

Soil Morphology

Soil morphology (e.g., a detailed description of soil profiles) provides the key to understanding and interpreting soils and landscapes at archaeological sites. The unique soil morphology of a given region and site results from the weathering processes regulated by the interaction of soil-forming factors.^[14] These factors are climate, biotic, geology, topography, and length of time that the weathering processes have been operating. The morphologic properties of soils usually described in excavations and their interpretation for archaeological sites are given in Table 1. A great deal of experience

and technique is needed to provide an accurate and informative soil description. Evaluation of the age of soils, e.g., requires an integration of all the morphologic features that are detailed in Table 1. Certain soil horizons provide general age estimates based on the length of time needed for weathering processes to develop specific features (e.g., argillic horizons). As noted in Table 1, a minimal argillic horizon can form in 4000 years. Other age estimates of soil horizons have been published previously.^[9,15]

One of the most useful applications of soil morphology in archaeological site interpretation is that of distinguishing “natural” from “artificial” or “man-influenced” horizons. Some natural horizons—such as a spodic (Bh) with a dark-colored, organic-rich matrix—may appear as a buried surface or midden. Some albic E horizons could be interpreted as ash layers. Other characteristics that are related to

Table 1 Morphologic properties of soils and their interpretive value at archaeological sites.

Soil property	Useful interpretative features
Texture	Lithologic and pedologic discontinuities; classification of geologic materials; determination of argillic horizons; determine relative energy of alluvial sedimentation
Structure	Relative abundance of macropores and potential artifact movement; degree of development is an indicator of soil age; development of clay or organic coatings on argillic horizons (e.g., continuous clay coatings on pedologic faces indicate 10,000 years of development while discontinuous coatings may indicate 4,000–5,000 years of weathering in Southeastern United States)
Color	Indicator of organic matter and free iron content; classification of sediments; delineation of horizons; drainage characteristics (redoximorphic features)
Boundary	Abrupt boundary indicator of Ap (plow zone) or modern deposition; boundary becomes more diffuse with age
Consistence	Indicator of structural development, cementation, or consolidation (e.g., modern alluvium usually very friable or loose)
Clay coatings	Coatings on peds or in pores indicate the state of development and age
Carbonate	Secondary CaCO ₃ leaching, coatings, pore filling, and cementation can provide soil age estimates and climatic implications
Horizon identification	Indicates many weathering processes occurring in profile, e.g., A=organic matter accumulation; E=leached zone; Bt=argillic horizon with minimal 4000 year age; distinguish natural vs. artificial horizons; horizon thickness (solum) is a measure of length of weathering time; diagnostic horizons useful indicator for archaeological interpretation (argillic, cambic, fragipan, spodic, etc.)

Source: Adapted from Foss, Lewis, et al.^[13]

soil genesis, such as redoximorphic features (i.e., mottling or gleying), result from water table fluctuations and often cause confusion in the interpretation of color in archaeological levels. Horizons with calcium carbonate (CaCO_3) filling (Bk or Ck) have sometimes been identified as plaster filled.

LABORATORY

Laboratory soil characterization for archaeological interpretations is used to verify and supplement field morphology. Laboratory analysis without complete soil morphology is generally of minimal value for archaeological interpretation. Complete sampling of all soil horizons, columns, or archaeological levels is also important to realize the full benefit of the additional cost and labor of soil analysis.

Those laboratory analyses that are frequently applied in pedoarchaeology are organic carbon,^[16] particle size distribution,^[17] and elemental composition.^[18] Other soil analysis may include pH, electrical conductivity, mineralogy, free iron, scanning electron microscopy (SEM), energy dispersive X ray (EDAX), CaCO_3 , and micromorphology. The micromorphologic studies by Goldberg^[19] and Macphail and Goldberg^[20] have been especially useful in interpreting site stratigraphy and pedologic and geologic events.

FUTURE

Pedologists have grown increasingly interested in the work on archaeological sites, and it is likely that this trend will continue well in the future. Although we aid archaeologists in understanding the soils and pedologic features they carefully excavate, we have learned a great deal about weathering rates, horizon formation, and landscape development by teamwork with archaeologists and geologists. The use of additional techniques or applications by geoarchaeologists, such as X-ray diffraction, SEM, EDAX, electrical resistivity, ground-penetrating radar, magnetic susceptibility, and micromorphology, will improve soil interpretation work in the future. Despite advances in analytical tools, the key to archaeological site interpretation is the accurate, complete soil morphologic descriptions.

Arid Soils

H. Curtis Monger

Abstract

Humans have lived on arid soils for millennia. Arid soils are important to humans for livestock grazing, irrigated agriculture, and urban development. In many arid regions of the world, human land use has resulted in desertification and diminishing groundwater supplies, both of which are increasingly important social and scientific issues as the human population increases.

INTRODUCTION

Scarcity of rain is the dominant characteristic of arid soils. While age, parent material, carbonate, and salt content may vary from arid soil to arid soil, dryness is common to all. Of the total ice-free land area on earth (130,797,000 km²), about 22% or 28,703,000 km² is occupied by soils with aridic moisture regimes.^[1]

Although arid (Latin: “aridus,” dry) signifies lack of moisture, technical definitions of arid vary. In some cases, the arid–semiarid boundary is placed at 25 cm (10 in.) of annual rainfall.^[2] In other systems, such as the Köppen–Geiger–Pohl and Meigs systems, the arid (desert)–semiarid (steppe) boundary is based on a combination of rainfall and temperature.^[3,4] Still other systems, such as those by Strahler and Soil Survey Staff, use soil moisture to define arid zones because the availability of moisture to plants is more important than annual precipitation itself.^[4,5] In all cases, however, rainfall is insufficient to maintain perennial streams. Soils in these regions are unique because relatively little water percolates deep enough to reach groundwater. As a result, carbonates, gypsum, and more soluble salts accumulate in the profiles of many arid soils.

ARID SOILS OF RIVER FLOODPLAINS

Floodplain soils along rivers that flow through arid climates were sites of several ancient and eminent civilizations. Sumerian (ca. 3600 B.C.) and later Babylonian (ca. 2000 B.C.) civilizations grew into centers of trade and government as a result of irrigated agriculture on the Tigris and Euphrates river floodplains.^[6] Likewise, soils and irrigated agriculture along the Nile of ancient Egypt, the Indus of ancient India, and the Hoang-Ho (Yellow River) of ancient China made it possible for civilizations to create notable schools, calendars, armies, mathematics, medicine, literature, philosophy, science, and art. Hohokam, Aztec,

and Inca societies emerged in arid and semiarid environments in the western hemisphere as well.^[7]

These civilizations existed because floodplain soils are well suited for irrigated agriculture if groundwater tables are sufficiently deep and salts do not accumulate. In the case of the Nile prior to dam construction, the river would rise and spill over its banks, flood the adjacent plain, deposit sediment, and leach salts.^[7] In the case of the Tigris and Euphrates, however, drainage canals were needed to carry away leached salts and with their demise soils became saline.

ARID SOILS ON UPLANDS

Most soils in arid regions are not on floodplains but occur in vast upland areas composed of the following three major landforms: mountains, piedmont slopes, and basin floors.^[8] These major landforms, in turn, are composed of smaller, component landforms. Typically, soil boundaries correspond to component landforms. In mountains, e.g., soil boundaries match the boundaries of colluvial wedges, valley fills, and pediments.^[9] On piedmont slopes, soil boundaries parallel the boundaries of alluvial fans, ballenas, and fan skirts. On basin floors, which characteristically have little topographic relief, soil boundaries generally follow landforms produced by wind, such as deflation blowouts, dunes, and eolian plains, or landforms produced by pluvial lakes, such as lake plains, playas, and beach plains.

Of the five soil-forming factors (climate, time, biota, topography, and parent material), climate is the defining factor of arid soils although time is an important factor as well. The impact of time on arid soils is revealed by the carbonate and clay accumulations in soils of progressively older geomorphic surfaces (Fig. 1). Carbonate in non-gravelly soils, e.g., progresses from carbonate filaments in middle Holocene soils to carbonate nodules in late Pleistocene soils to carbonate-indurated horizons in middle Pleistocene soils.^[10] Clay likewise accumulates with time

Fig. 1 Desert piedmont slope rising to a mountain chain in Southern New Mexico. Progressively older geomorphic surfaces with progressively greater soil development are the typical features of piedmont slopes. The younger soil on the right (about 3000 years old) has a small amount of carbonate (white zone in profile). The older soil to the left (25,000–150,000 years old) has substantially more carbonate. In addition, the older soil has an argillic horizon overlying the carbonate horizon.

to form argillic horizons. However, the correlation of clay accumulation with time is less robust than that of carbonate accumulation with time because many ancient soils that have calcretes do not have argillic horizons.^[11] This indicates that argillic horizons are more vulnerable to obliteration by erosion and bioturbation than calcic or petrocalcic horizons.

Arid soils are unique not only because carbonate, gypsum, and soluble salt accumulate, but also because many have vesicular A horizons covered by desert pavement^[12] or microbiotic crust.^[13] In addition, inadequate water and nitrogen suppress biomass production on arid soils to about one-tenth the biomass of temperate forest soils.^[14] Nevertheless, soil animals such as rodents, ants, and termites are common. Ants, e.g., can transfer 80 g m⁻² of desert soil to the land surface per year, which is as much as ants transfer in more mesic environments.^[15]

TYPES OF ARID SOILS

The main criterion for the classification of arid soils is soil dryness, or the aridic (torric) moisture regime,

which is defined as soils too dry for agricultural crops unless irrigated.^[16] Further taxonomic subdivisions are based on diagnostic horizons. In contrast to the notion that arid soils are poorly developed, as written in some soil science books, many arid soils are strongly developed with a variety of diagnostic subsurface horizons.^[17] These horizons include the argillic, natric, salic, gypsic, petrogypsic, calcic, and petrocalcic horizons and the duripan.^[5] Diagnostic surface horizons include the ochric epipedon with minor occurrences of the mollic and anthropic epipedons.

Arid soils that have diagnostic subsurface horizons are generally classified as Aridisols. These include many of the older soils on piedmont slopes, basin floors, and mountain uplands. Various types of Aridisols occur on the landscape because of lateral changes in the particle size, truncation of diagnostic horizons, degradation of diagnostic horizons, moisture heterogeneity across the landscape, and age differences, which can range from Historical to Pliocene within small geographical areas.^[9,18]

Arid soils that lack diagnostic subsurface horizons are generally classified as Entisols, which fall into the azonal

Fig. 2 The illustration of Soil Taxonomy Suborders and Great Groups that have aridic moisture regimes (shaded) and their moister counterparts that have ustic and xeric moisture regimes. **Source:** From Soil Survey Staff.^[5]

concept of Sibirtsev.^[19] These include many of the younger soils on floodplains, dunes, and erosional surfaces. In Soil Taxonomy, floodplain soils are mainly classified as fluvents or, more specifically, torrifluvents.^[5] Arid soils associated with dunes are commonly torripsamments, and those associated with erosional surfaces are commonly torriorthents.

Aridisols (14,942,000 km²) and Entisols (12,682,000 km²) are the dominant soil types in arid regions although other soil types include Vertisols (889,000 km²) and Oxisols (31,000 km²) and very minor amounts of Mollisols, Andisols, Histosols, and Spodosols.^[1] Arid soils grade into semiarid soils across the following three climatic transects: laterally into wetter regions, upslope into wetter climates at higher elevations, or downslope into run-in areas with wetter microclimates. Taxonomically, changes in soil types from dry region aridic to wetter region ustic or xeric moisture regimes are expressed at the Suborder and Great Group level (Fig. 2). Linked to this climatic transition is a progressive change in vegetation—desert shrublands give way to grasslands that in turn give way to woodlands.

Also across this transition, soils have progressively deeper carbonate horizons. In the Chihuahuan Desert, for instance, carbonate zones are 50 cm deep at 230 mm of annual rainfall and 100 cm deep at 320 mm of annual rainfall.^[20] Likewise, gypsum zones progressively deepen from about 50 cm depth at 150 mm of annual rainfall to about 100 cm depth at 250 mm annual rainfall.^[21] Accompanying an increase in rainfall is an increase in soil organic matter. Although the amount of organic matter depends on the clay content, organic matter ordinarily increases from less than 0.5% in A horizons of arid shrubland soils to 2–5% in semiarid and subhumid grassland soils.^[22]

ECOLOGICAL SIGNIFICANCE

Biodiversity in arid regions is linked to habitat diversity. Habitat diversity, in turn, is created by various microclimates caused by topographic factors and soil properties.^[23]

Thus, soils help mold and are molded by ecosystems. In many arid regions, such as the Southwestern United States, soils have been impacted by ecosystem changes of the Holocene and late Pleistocene when wetter climates alternated with drier climates.^[24–27] According to this model, landscape stability was greater during wetter climates because denser vegetative cover reduced erosion. With reduced erosion, soil formation occurred. In contrast, instability was greater during drier climates because sparse vegetative cover gave rise to more bare ground and increased erosion. With increased erosion, soil formation was inhibited. This oscillation between stability and instability is recorded as stacked sequences of buried Paleosols in depositional environments and as stepped sequences of fan terraces in areas that grade to fluctuating river base levels.

Globally, arid soils affect atmospheric dust, rain chemistry, ocean fertilization, albedo, denitrification, and the carbon cycle as both sinks and sources of carbon dioxide.^[28,29] Carbonate-carbon, for instance, is the second largest terrestrial carbon pool, totaling approximately 50–60 Pg C in the dryland zones of the United States^[30] and approximately 750–950 Pg C in the dryland zones of the world.^[31]

Humans have lived on arid soils for millennia. In fact, the oldest known hominid tools are in arid East Africa and date back 2.5 million years.^[32] Arid soils are important to humans for livestock grazing, irrigated agriculture, and urban development. In many arid regions of the world, human land use has resulted in desertification and diminishing groundwater supplies, both of which are increasingly important social and scientific issues as human population increases.

Callaghan, New South Wales, Australia*

Abstract

Groundwater contaminated with arsenic (As) and its associated health dangers for people have been reported worldwide, particularly in the countries of Southeast Asia. This study presents a literature-based overview of the As contamination in this region where groundwater is contaminated with naturally occurring As. As a consequence of using contaminated water for irrigation, As is also deposited in agricultural soils and potentially contaminates food crops grown in this region. To minimize the risk of As contamination from affected groundwater and soil, simple, practical, and cost-effective solutions need to be implemented urgently.

INTRODUCTION

Arsenic (As) is a metalloid widely distributed in the earth's crust. It is recognized as a toxic element and has been classified as a human carcinogen affecting skin, lungs, and other internal organs.^[1] Elemental As is a member of Group VA on the periodic table, with nitrogen, phosphorus, antimony, and bismuth. Its atomic number is 33, and it has an atomic mass of 74.91. It can exist in four valence states: -3 , 0 , $+3$, and $+5$. Under reducing conditions, arsenite [As(III)] is the dominant form; arsenate is generally the stable form found in oxygenated environments.^[1] Arsenic and its compounds occur in crystalline, powder, and amorphous or vitreous forms. It usually occurs in trace quantities in all rock, soil, water, and air.^[1]

The bioavailability and toxicity of As depend on its chemical form. In general, the inorganic forms of As are much more toxic than the organo-As forms. Organo-As species are common in marine organisms. The major As compound in marine animals is arsenobetaine. Two minor As compounds (tetramethylarsonium and arsenocholine) are commonly found in marine animals. However, some organic As species such as monomethylarsonous acid (MMA[III]) and dimethylarsinous acid (DMA[III]), which have been identified in urine, are also very toxic.^[1]

The occurrence of elevated concentrations of As has been detected in numerous aquifers around the world where As concentrations in groundwater exceeded the World Health Organization (WHO)-recommended value of As ($10 \mu\text{g/L}$) in drinking water. Significant As exposure mostly occurs through drinking As-contaminated water and food crops irrigated with As-contaminated water. Inorganic As exposure at chronic levels adversely impacts on human health, causing skin disorders, cardiovascular disease,

neurological complications, reproductive disorders, respiratory effects, diabetes mellitus, as well as various types of cancers including skin, lung, bladder, and kidney.^[2,3] The Southeast Asian countries that are affected by As in groundwater include Bangladesh, several states of India (i.e., West Bengal, Bihar, Uttar Pradesh, Jharkhand, Assam, Chhattisgarh, and Manipur), Nepal, Myanmar, Pakistan, Vietnam, Lao People's Democratic Republic (Lao PDR), Cambodia, lowlands of Sumatra in Indonesia, and several provinces of China.^[4–6] Several European countries, e.g., Spain, Portugal, and Hungary, are also As-contaminated.^[7] In South and North America, the most notable problems with As in groundwater have been detected in several areas of the United States of America, Canada, Mexico, Nicaragua, Ecuador, Chile, Argentina, Peru, Brazil, and Uruguay.^[8] In the Ganges Delta region of Bangladesh and West Bengal, As in groundwater has emerged as the largest environmental health disaster; it has been estimated that more than 100 million people are at risk from As poisoning. A study conducted by the World Bank found that about 0.7 million people have so far been affected by As-related diseases in South and East Asia.^[9] In this entry, we present a literature-based overview of major As contamination in groundwater and soils from various regions located in Southeast Asian countries.

EXTENT AND SEVERITY OF As IN GROUNDWATER OF BENGAL DELTA

Bangladesh

In a nationwide survey conducted by the British Geological Survey along with the Department of Public Health

Engineering (DPHE), Bangladesh, 3534 tube well samples were analyzed from all over Bangladesh except Chittagong Hill Tract. It was reported that 46% and 27% of the samples exceeded 10 and 50 $\mu\text{g/L}$ of As, respectively.^[10] It was also estimated that 57 million and 35 million people could be drinking As-contaminated water with concentration above 10 and 50 $\mu\text{g/L}$, respectively.^[10] Reports emerged of As concentrations ranging from 0.07 to 640 $\mu\text{g/L}$, based on 112 groundwater samples from throughout Bangladesh.^[11] Another study analyzed 6500 tube wells samples from the Araihaazar area of Narayanganj in 2000–2001 and concluded that half of the samples contained As above 10 $\mu\text{g/L}$ and one-quarter contained As above 50 $\mu\text{g/L}$.^[12]

In a large study, it was reported that 27.2% and 42.1% of the tube wells had As above 50 and 10 $\mu\text{g/L}$, respectively, based on an analysis of 52,202 water samples from hand tube wells from all 64 districts of Bangladesh since 1996.^[13] This involved employing flow injection–hydride generation atomic absorption spectrometry method for As measurement.^[13] An analysis of scenarios of As status including As-related health effects in Bangladesh was reported based on the authors' 21-year study.^[14]

A study showed that chronic As exposure through drinking water was associated with an increase in the mortality rate based on the Cox proportional hazards model to estimate hazard ratios mortality.^[15] In that study, authors interviewed in person and clinically assessed 11,746 participants (aged 18–75 years) from the Araihaazar area. The study found that 407 deaths were ascertained between October 2000 and February 2009. Multivariate adjusted hazard ratios for all-cause mortality in a comparison of As at concentrations of 10.1–50.0, 50.1–150.0, and 150.1–864.0 $\mu\text{g/L}$ with at least 10.0 $\mu\text{g/L}$ in well water were 1.34 [95% confidence interval (CI), 0.99–1.82], 1.09 (95% CI, 0.81–1.47), and 1.68 (95% CI, 1.26–2.23), respectively.^[15]

West Bengal

One study reported that 48.1% had As above 10 $\mu\text{g/L}$ and 23.8% had As above 50 $\mu\text{g/L}$, based on 140,150 water samples analysis from tube wells in all 19 districts, and the estimated population drinking As-contaminated water with concentration above 10 and 50 $\mu\text{g/L}$ were 9.5 and 4.2 million, respectively.^[16] Another large-scale survey was carried out by the Public Health Engineering Department (PHED), Government of West Bengal, with the support of United Nations Children's Emergency Fund (UNICEF). This involved eight districts (i.e., North 24 Parganas, South 24 Parganas, Murshidabad, Nadia, Bardhaman, Hawrah, Hooghly, and Malda) and water was analyzed using the silver diethyldithiocarbamate method.^[17] Altogether, water samples from 132,262 tube wells were analyzed, and 25.5% of them contained As greater than 50 $\mu\text{g/L}$ and 57.9% greater than 10 $\mu\text{g/L}$.^[17]

ARSENIC CONTAMINATION IN GROUNDWATER IN OTHER REGIONS OF SOUTHEAST ASIA

Other Areas in India

In a study, it was reported that around 20,000 tube well water samples were analyzed from 12 districts of Bihar state; 32.7% samples contained As above 10 $\mu\text{g/L}$, while 17.8% had As above 50 $\mu\text{g/L}$.^[18] It was also estimated that around 3.1 million and 1.7 million people are potentially at risk from consuming As-contaminated water from Bihar.^[18] In Uttar Pradesh, around 5500 tube well water samples were examined from five districts; 44.4% samples contained As above 10 $\mu\text{g/L}$, and 26.2% had As above 50 $\mu\text{g/L}$.^[18] Approximately 0.6 million people are exposed to As-contaminated water with concentration above 50 $\mu\text{g/L}$.^[18] It has been reported for Jharkhand that around 3500 tube well water samples investigated from five districts and 36.1% of them contained As above 10 $\mu\text{g/L}$; furthermore, 15.4% had As above 50 $\mu\text{g/L}$.^[18] In Assam and Manipur, 1590 and 628 tube well water samples were analyzed. About 42.3% and 63.3% of samples had As above 10 $\mu\text{g/L}$, while 19.1% and 23.2% had As above 50 $\mu\text{g/L}$ from Assam and Manipur, respectively.^[18]

The quality of groundwater with respect to As from 33 different sources in the predominantly rural area of Golaghat subdivision in Golaghat district of Assam (India) was determined during the premonsoon (February) and postmonsoon (October) seasons of 2008.^[19] The As concentrations varied from not detectable to 220 $\mu\text{g/L}$ during premonsoon and from 1 to 187 $\mu\text{g/L}$ during postmonsoon. The high values of As were observed in Forkating, Fatual (220 $\mu\text{g/L}$), and Bahbari (187 $\mu\text{g/L}$) in premonsoon and postmonsoon seasons, respectively.^[19]

China (Including Taiwan)

The distribution and chemical characteristics of high-As groundwater, hydrogeological settings of high-As groundwater aquifers, and the geochemical processes controlling As distribution in typical areas of China were reviewed (the study by Guo et al.^[20] and references therein). It was reported that out of 34 provinces, high As was reported in the groundwater of 20 provinces. Generally, there are two types of areas where high-As groundwater naturally occurs. One is the arid–semiarid inland basins, and the other is the river deltas.^[20] Concentrations of As above 50 $\mu\text{g/L}$ have been detected in groundwater in aquifers of the Hohhot basin (depth: 4–400 m; As range: <1–1860 $\mu\text{g/L}$) and the Hetao basin (depth: 10–30 m; As range: <1–969 $\mu\text{g/L}$) of Inner Mongolia.^[20] The ranges of As in aquifers of the Datong (depth: 20–50 m), the Taiyuan (depth: 50–200 m), and the Yuncheng (depth: 20–300 m) basins of Shanxi Province were reported as <1–1300, 0.1–116, and 0.1–500 $\mu\text{g/L}$, respectively. The concentrations of As in aquifers of Songnen basin in Jilin

Province and Yinchuan basin in Ningxia Province ranged from <1 to 360 µg/L and <0.1 to 200 µg/L, respectively. It was also reported that the aquifer of Dzungaria basin of Xinxiang Province had As concentration between 70 µg/L and 850 µg/L.^[20]

Elevated concentrations of As have been found in several river deltas, e.g., Yangtze River delta of Shanghai and Nanjing, Yellow River delta of Shandong Province, Pearl River delta of Guangdong Province, Chianan alluvial plain of Taiwan, and Lanyang alluvial plain of Taiwan (the study by Guo et al.^[20] and references therein). The concentrations of As in river deltas varied from 0.22 to 3590 µg/L. High levels of As contamination up to 2160 µg/L have also been detected in the mountain areas such as Qinghai, Gansu, Sichuan, and Yunnan.^[20]

Indonesia

A study analyzed 97 samples of five distinct groups of groundwater composition that reflect a variety of geological sources and/or chemical conditions (pH and redox) from Sumatra.^[6] Arsenic concentrations showed a heterogeneous distribution over the study area, with 12 out of 97 samples from the tube wells exceeding the WHO guideline value for drinking water (10 µg/L). Elevated As levels were mostly present in the groundwater of tube wells located in Holocene deposits. The lowest concentrations were measured in groundwater (oxidizing conditions), while the highest values occurred in areas with Holocene swamp and alluvial sedimentation. The average (range) As concentrations in five areas detected were 5.8 (<0.1–34), 0.5 (<0.1–3.8), 7.2 (<0.1–35), 9.8 (0.2–65), and 2.6 (<0.1–22) µg/L, respectively.^[6]

Lao PDR

Arsenic concentrations in tube well water collected from several provinces (e.g., Attapeu, Bolikhamxay, Champasak, Savannakhet, Saravane, and Vientiane) of Lao PDR were determined, and the results showed that As-contaminated areas were mostly floodplains in the central and southern parts of the country. Total As concentrations ranged from <0.5 to 278 µg/L, with over half exceeding the WHO guideline concentration of 10 µg/L and As(III) were present in 46% of water samples.^[21]

Myanmar

A study confirmed the presence of elevated levels of As in groundwater of Myanmar.^[22] Altogether 55 wells water were analyzed by visual field kit measurements, and the results reveal that a total of 23 wells met the WHO guideline concentration for As (10 µg/L), another 9 wells had As concentrations up to 50 µg/L, and 23 wells recorded >50 µg/L of As. It was also reported that elevated concentrations of As (50–630 µg/L) were determined in wells up

to 60 m deep. Another study assessed samples from 18 drinking water wells (12 in Myingyan city and 6 in nearby Tha Pyay Thar village) of Myanmar for As and reported that the ranges of As concentrations in Myingyan city and nearby Tha Pyay Thar village were 1–22 and 10–134 µg/L, respectively.^[23]

Nepal

In 2003, it was reported that 23% of samples exceeded As >10 µg/L, and 5% were above the “Nepal Interim Arsenic Guideline” concentration of 50 µg/L, based on an analysis of 15,000 tube wells.^[24] It was estimated that around 0.5 million people in Terai were at risk of As poisoning (>50 µg/L).^[24] An analysis of 42 deep and 13 shallow groundwater samples from Kathmandu valley showed that As levels in shallow groundwater are usually <10 µg/L, but 52% of the deep groundwater had As >10 µg/L.^[25] Screening of tube wells in the Terai region of Nepal started in 2001, and several organizations tested 737,009 groundwater samples from 25 districts.^[26] Of these, 82.6% contained As ≤10 µg/L, 7.6% had As >10–50 µg/L, and 2.6% had As >50 µg/L.^[26] It was also reported that in 2011 about 2.29 million and 0.37 million people are expected to drink water with As concentrations of 10–50 and >50 µg/L, respectively.^[26] In 2011, it was reported that out of 24,674 tested wells in the Nawalparasi district, approximately 7896 wells (32%) had As concentrations greater than 10 µg/L, and 3676 wells (14.9%) had As concentrations greater than 50 µg/L.^[27]

Pakistan

The concentration of As in groundwater (n = 153) ranged from 13 to 106 µg/L in Jamshoro district of Pakistan.^[28] The study concluded that As may originate from coal combustion at brick factories and power generation plants, and it was mobilized promotionally by the alkaline nature of the understudy groundwater samples.^[28]

Thailand

Groundwater samples were collected from 20 different sampling points between August 2009 and February 2010 in two areas (i.e., Amphoe Khemmarat and Ubon Ratchathani) of Thailand, and the concentration of As in the groundwater of Amphoe Khemmarat ranged from 0.7 to 20.2 µg/L with an average value of 4.79 µg/L.^[29]

Vietnam and Cambodia

Groundwater samples were analyzed during 2007–2008 in the Mekong River delta in Vietnam and revealed that 26% of samples had above 10 µg/L of As.^[30] Concentrations of As ranging from <0.1 to 1351 µg/L and elevated levels of As were found in groundwater at sampling sites close to the

Mekong River and in wells less than 60–70 m deep. Sediment samples from An Giang and Dong Thap had 18 and 38 mg/kg, respectively, of As concentrations. Arsenic sediment occurred mainly in the poorly crystalline iron (Fe) oxide phases.^[30] Concentrations of As in the groundwater collected at Gia Lam district and Thanh Tri district, suburban areas of Hanoi, Vietnam, ranged from <0.10 µg/L to 330 µg/L, with about 40% of these exceeding the WHO drinking water guideline concentration of 10 µg/L.^[31] One study presented an overview of groundwater As pollution in the Mekong River delta; As concentrations ranged from 1 to 1610 µg/L in Cambodia (average: 217 µg/L) and 1 to 845 µg/L in southern Vietnam (average: 39 µg/L), respectively.^[32] Of the studied wells, 48% had As concentrations >10 µg/L in shallow aquifers in the south of Phnom Penh situated at the Cambodian floodplain.^[33] Another study investigated the concentrations of As in groundwater from three villages in the Kandal Province of Cambodia and reported that As concentrations ranged from 6.64 µg/L to 1543 µg/L, with average and median concentrations of 552 and 353 µg/L, respectively.^[34] About 86% out of 15 samples contained As concentrations exceeding the WHO drinking water guideline concentration of 10 µg/L.^[34]

Arsenic concentrations in groundwater ranged from 0.1 µg/L to 1340 µg/L, with 37% of the studied wells exceeding the WHO guideline As concentration of 10 µg/L, based on its transnational groundwater survey of the 62,000 km² Mekong River delta floodplain (southern Vietnam and bordering Cambodia).^[35] Arsenic contamination in groundwater in four villages (i.e., Vinh Tru, Bo De, Hoa Hau, and Nhan Dao) of Ha Nam Province in northern Vietnam revealed that concentrations of As in three of these villages (i.e., Vinh Tru, Bo De, and Hoa Hau) significantly exceeded the Vietnamese drinking water standard for As (10 µg/L) with average concentrations of 348, 211, and 325 µg/L, respectively.^[36] It was also determined the distribution of As in the groundwater from two regions (i.e., Tien Giang Province and Dong Thap Province) of the Mekong River delta and reported that the concentration of total As in the groundwater, which is used for the drinking water supply, ranged from 0.9 to 321 µg/L, and 27% of the shallow well water samples exceeded the WHO provisional guideline concentration of 10 µg/L.^[37]

ARSENIC IN SOILS

Arsenic concentrations in soils were reported to be as high as 57 mg/kg in four different districts (i.e., Chapai Nawabganj, Kushtia, Pabna, and Jamalpur) in Bangladesh.^[38] The range of As in paddy soil was 4.7–52 mg/kg with an average of 17.2 mg/kg (mean As concentrations in highland and medium highland soils were 14 and 21 mg/kg, respectively), based on 263 paddy soils (both highland and medium highland) irrigated with As-contaminated water (average: 130 µg/L; range: <2–458 µg/L) from Tala of

Satkira, Bangladesh.^[39] The study concluded that soil As in highland paddy soils was related to As and Fe levels of irrigation water and duration of contaminated wells in operation.^[39] A study reported that out of 31 soil samples evaluated from various locations of As-contaminated districts in Bangladesh, results showed that all soils contained As below 10 mg/kg.^[40] In 2003, it was reported that As levels in surface paddy soils (0–15 cm) of Bangladesh varied between 3.1 and 42.5 mg/kg.^[41] The highest levels of As were reported in districts to the west of Bangladesh, particularly Meherpur, Chuadanga, Kushtia, and Rajbari, all having one or more soil samples with As >30 mg/kg. Concentrations of As in soil in the range of 20–30 mg/kg are distributed throughout the central belt of Bangladesh.^[41] The concentrations of As in soils from the command area of the tube wells situated in southwestern Bangladesh ranged from 4.5 mg/kg to 68 mg/kg; more than 85% of these soils contained <20 mg/kg of As.^[42] At the Marua and Samta villages in the Jessore district of Bangladesh, the As concentrations ranged from 1.2 mg/kg to 14.8 mg/kg in surface soil.^[43]

A study showed that the average As concentrations were 33.15 and 6.10 mg/kg in the soils collected from Faridpur and Dhamrai, respectively.^[44] The average As concentration in Faridpur was more than 3 times higher than the world standard (10 mg/kg) for soil.^[44] Average As concentration was 13.3 mg/kg at Samta village, one of the As-rich areas of Bangladesh.^[45] A study determined As contamination of 30 selected soils at three depths (i.e., 0–15, 15–30, and 30–45 cm) in 10 thanas of four As-affected districts (i.e., Gopalganj, Faridpur, Rajbari, and Madaripur) of Bangladesh.^[46] The ranges of As in the soils of all four districts were 3.96–25.09, 0–38.67, 1.32–36.99, and 1.32–38.19 mg/kg, respectively.^[46]

The average concentration of As in rice field (irrigated with As-rich groundwater) was 101 mg/kg in West Bengal, India.^[47] The average As concentrations in soils was 5.31 mg/kg (range: 2.68–6.79 mg/kg) and 10.7 mg/kg (range: 3.34–31.6 mg/kg) collected from fallow lands (n = 86) and agricultural lands (n = 30) of Domkal block in the Murshidabad district of West Bengal.^[48] The mean As concentrations in surface soils, soils from the roots of plants, soils below ground level (0–30 cm), and all soils from the four agricultural lands were 14.2 mg/kg (range: 9.5–19.4 mg/kg, n = 99), 13.7 mg/kg (range: 7.56–20.7 mg/kg, n = 99), 14.8 mg/kg (range: 8.69–21 mg/kg, n = 102), and 14.2 mg/kg (range: 7.56–21 mg/kg, n = 300), respectively.^[49]

Soil samples (n = 73) from the Singe Tsangpo (upstream of the Indus River), Yarlung Tsangpo (upstream of the Brahmaputra River), and other drainage basins in Tibet were analyzed in 2008.^[50] The average As concentration in soils was 44 ± 27 mg/kg (n = 28; range: 12–84 mg/kg) for the Singe Tsangpo, and it was 30 ± 34 mg/kg (n = 21; range: 6–173 mg/kg) for the Yarlung Tsangpo.^[50] The soil As levels from an alluvial plain of the Mangyeong River,

Korea, ranged from 3.9 to 9.9 mg/kg.^[51] The total soil concentrations of As in soil collected from paddy fields in the suburban areas of some major cities in Fujian Province, southeast China, ranged from 1.29 to 25.28 mg/kg with an average of 6.04 mg/kg.^[52] The total As concentration in 11 tested soil samples ranged from 11.8 to 112 mg/kg from the northern part of the Chianan Plain in southwestern Taiwan.^[53] The As concentrations in all soil samples except one notably exceeded the background level of As (18 mg/kg) in the rural soils of Taiwan. Another study found total As content ranging from 7.92 to 12.7 mg/kg in surface soils collected from the coastal part of Chianan Plain in southwestern Taiwan.^[54]

Total As in the soils collected from 3 As-contaminated areas (18 samples per area) at different distances (0, 400, and 800 m) in Iran ranged from 105.4 to 1500 mg/kg.^[55] The As concentrations of 0–20 cm and the 20–40 cm soil layers were comparable, and there was no consistent decline in soil As concentration when distance increased.^[55]

A study measured Arsenic levels in agricultural soils (surface: 0–5 cm and subsurface: 20–25 cm) located in the Red River delta in northern Vietnam.^[56] Soil samples were collected from 18 paddy and 6 upland fields on both sides of the river. The total As contents of approximately 80% of the surface paddy and upland soils exceeded the maximum allowable limit for Vietnamese agricultural soils (12 mg/kg). Arsenic contents higher than 35 mg/kg were found in soils from the Hung Yen and Ha Nam Provinces, where high As levels in the groundwater have also been reported.^[56] Another study investigated the concentration of total As in soil (0–15 cm depth) from 15 selected locations in Phumi Khleang, Kandal Province, Cambodia. The As concentrations in soils varied from 5.34 to 27.81 mg/kg.^[57] A study evaluated the As content of soils from five provinces (i.e., Kandal, Prey Veng, Battambang, Banteay Meanchey, and Kampong Thom) in Cambodia's rice-growing regions and reported that the total soil As concentrations ranged from 0.8 µg/g to 18 µg/g. Significant differences were documented for these provinces ($P < 0.0001$), with Banteay Meanchey and Battambang having lower soil As than Kandal and Prey Veng.^[58] Sediments of 12–40 m deep cores from the Red River delta of Cambodia contained As levels of 2–33 µg/g (average 7 µg/g, dry weight) and demonstrated a remarkable correlation with sediment-bound Fe.^[33]

CONCLUSION

Naturally occurring As has been detected in groundwater in many parts of the world, and it is evident that the countries of Southeast Asia are highly contaminated area. The soils irrigated with As-contaminated water also contained considerable amounts of As. Consequently, crops and in particular paddy rice that is cultivated on contaminated lands accumulate high levels of As. Effective remedial

strategies for water, soil, and food crops grown in contaminated soils are urgently required to prevent or minimize the exposure of As to humans.

Art and Soil

Christian Feller

Institute of Research for Development, Montpellier, France

Abstract

This entry is a chronological short history of Western art (mainly paintings) from prehistory to the contemporary period through the word “Soil.” The conclusion is that the vision of Soil (in a scientific meaning), as an independent work of art, is contemporary.

SOIL IN ART

It is widely accepted that humans have always considered the natural environment a subject of great interest to art. Early pictorial examples include cave paintings done by Cro-Magnon man during the Upper Paleolithic, about 30,000–40,000 years ago. However, the vision of Soil (in a scientific meaning), as an independent work of art is contemporary and extremely rare in the world of painting. For many years, artists have depicted actual or imaginary landscapes from which the trained eye of a pedologist, agronomist, or geographer can recognize a schematic view of what is commonly called soil but not Soil (as a Soil profile). This communication will show: 1) the representations of Soil or soil in Western art from the Paleolithic to the modern era; and 2) some contemporary artworks where the Soil is considered as the main subject and has its goal to present Soil in art from Genesis (the Bible) to Pedogenesis (the scientific approach of the Soil formation from the Greek word *Pedon* meaning soil).^[1,2]

When Soil Is Depicted By Chance in the Landscape: The Soil as a Surface

In the biblical Genesis story of world creation, the whole of humanity is “soil” as Adam—meaning “soil” in Hebrew—was created from red dust and returned back to it. To a large extent, the representation of soils, as even a single line of soil surface, is neglected in Upper Paleolithic cave paintings.

The few extremely schematic representations inherited from the Assyrian civilization (from the 11th century to 7th century B.C.) depict natural scenes in which the soil surface is represented by schematic rocks and hillocks, drawn as shaped curves.^[3] In Grecian art, very few traces of soil representation have been found, except for frescoes of Aegean art coming from Santorini dating from the 5th century B.C.^[4] Wall paintings were widespread in the Roman civilization as decorative art designed in a truly realistic style that would never be seen again until the Early

Renaissance. At Pompeii, nature was represented through flowers and birds as well as other animals. However, relatively few representations of the landscape stood the test of time.^[4] They were probably simply lost.

From the Byzantine period of the early Middle Ages (the 6th century), many mosaics depicted rocky landscapes. However, between the 5th and 12th centuries, the representations of soil surface or landscapes are very often strongly schematized with undulating lines or hillocks, as in religious miniatures.

The Florentine painter Giotto (1266–1337) made a decisive break with the static Byzantine style, introducing realism. His paintings of rocky landscapes were among the first that included some perspective. Other Italian painters from the contemporary Giotto’s Sienese School developed a similar naturalistic style: Duccio di Buoninsegna (1260–1318), Simone Martini (1284–1344), and the Lorenzetti Brothers (1280/1285–1348).

During the Renaissance, the soil, as a surface, is generally represented in a highly realistic way, even for symbolic and/or imaginary landscapes. Such realism sometimes allows one to discern the Soil profile with different colors given to the surface soil and to deep horizons, as, e.g., in the works by Hans Memling (1430–1494) of “The Last Judgment” (ca. 1470)^[5] and Hieronymus Bosch with his “St. John the Baptist” (ca. 1500).

When Soil Is Depicted By Choice in the Landscape: The Soil as a Profile

The following three reasons motivated the representation of a soil profile: to explain the resurrection of the dead, to display the roots, and to show ploughing.

In “The Last Judgment” by Rogier Van der Weyden (1432), the resurrection of dead required the artist to show the Soil profile. The complete painting exhibits numerous such soil profiles.

In the paintings of the Renaissance, the representation of a ditch or a soil cut in a painting served very often as an excuse to picture roots. In the “St. John the Baptist” by

Hieronymus Bosch (1450–1516), the figure of St. John leans toward a sharp vertical exposure of soil, which includes a strange large root.^[6] A large root also appears in “The Tempest” painted by Giorgione (1477/1478–1510)^[7] and in “The Fall of Icarus” by Pieter Bruegel the Elder (1525–1569), just at right and behind the ploughman. These works were just some examples of paintings in which large forked roots were made evident. The representation of roots was not due to chance, but chosen for its symbolic value, and referred to the mandragora as suggested by Marijnissen and Ruyffelaere.^[8] The perception of mandragora as the subject of superstitions was presented in the *Encyclopédie des Symboles*^[9] through the following comments:

Mandragora is a plant with a high symbolic value, inspiring both fear and fascination. Its forked root which crudely resembles the human form has been credited since ancient times with a divine origin. It is considered as a universal medicine. The mandrake grows only at night, releasing some toxins (hyoscyamine, atropine, scopolamine) with a narcotic effect. For this reason, the root was used by medieval witches to concoct potions, and it played a remarkable role in the occult practices. According to the legend, the root grew only beneath gallows trees, as it was believed to be produced from the semen involuntarily ejaculated by a hanged man. It has to be gathered with high caution, and it was said that the mandrake gave forth an extremely piercing and fatal cry. It was uprooted, therefore, by a dog that died immediately after. During antiquity, the mandrake was considered as one of the attributes of the sorceress Circe. The root was used by the Jews to overcome infertility. In general, mandrake was associated with black and supernatural forces that man would approach with many precautions.

From the 14th to the 15th centuries, especially in the “Très Riches Heures” and the “Calendriers” (calendars), we see the representations of agricultural tasks and toils. Here, the soil is depicted with a clear concern of realism and technical specificity, including the tilling of the soil. In addition to this example, Pieter Bruegel the Elder (1525/30–1569) might be newly cited for “The Fall of Icarus.” Icarus is the tiny figure at the bottom on the right-hand corner, with only his legs visible, while in forefront of the canvas, attention is centered on the good Flemish ploughman tilling furrows. That was the triumph of daily working life over Utopia (“falling from the sky”).

THE SOIL BY HIERONYMUS BOSCH AND HIS DISCIPLES

The work of Hieronymus Bosch (ca. 1450–1516) abounds in “earth” and “bare soil” representations as seen in the “The Temptation of St. Anthony.” The soil in Bosch’s work was represented not only as a surface, but often either as a Soil profile in a slope cut (see above) or in adobes that are

associated with thatched roofs. Here, the artist emphasized the decomposition and decay of the sides of huts, in the same way that plant debris is decomposing on the top of the soil. The whole of Bosch’s work is influenced by “decomposition,” and soil depiction contributes to this process. The work of Bosch would deserve an independent study of his “soil” or “Soil” vision.

As Hieronymus Bosch is said to have been an inspiration for the surrealist movement of the 20th century, some surrealists might be considered as his disciples throughout their vision of soil or earth’s uses, e.g.:

- Salvador Dalí with “Soft Construction with Boiled Beans: Premonition of Civil War” (1936. Oil on canvas), Museum of Art, Philadelphia,^[10] “The Spectre of Sex-Appeal” (1934. Oil on canvas), Gala-Salvador Dalí Foundation, Figueres, Spain,^[11] or the “Metamorphosis of Narcissus”^[12];
- Yves Tanguy with the “Extinction of Useless Lights” (“Extinction des lumières inutiles”; 1927. Oil on canvas);
- Jean Dubuffet with “The Magician” (1954. Slag and roots, including slag base), both on view at the Museum of Modern Art, New York.^[13]

THE SOIL: HISTORY

Paintings during the 16th, 17th, and 18th centuries reached realistic excellence in representing the soil surface that could never be equaled. During this period and until the 20th century, artists did not consider the Soil as a chief subject, not even the impressionists who rendered it only as a landscape component.

During the 20th century, the soil surface was well represented in the land art movement. Soil is depicted as an object per se especially by some naturalists, agronomists, pedologists, and others who have developed a substantial artistic talent besides their scientist’s profession. Many works of contemporary artists—paintings, sculptures, performances, or art installations—centered on the Soil can be seen at Wessolek’s Web site,^[1] particularly, women artists, such as Ulrike Arnold, Pablia Velarde, Janis Lang, Betty Beier, Birgit Kratzhaller, and Kathryn Miller, who have led the way in using soil and geologic material as a means of artistic expression.

CONCLUSION

Our look at soil or Soil in art confirmed that in Western culture, most artists did not view soil as the complex and subtly beautiful medium that holds the interest of agronomists or pedologists. It was usually only considered as a surface. The belowground layers were generally not represented, while rocks and other natural objects fascinated artists. However, as underlined by the conclusion in

Jenny^[14]: “Whoever said that soils lack beauty is behind the times. Soil in art has arrived. It is an enrichment of art that is here to stay.”

Finally, it is predicted that we will increasingly see more artists and soil scientists interacting at the interface of their expertise and consciousness to produce images and objects that will capture the attention of audiences. If a successful exhibition on “the Soil” could be hosted by the Grand Palais in Paris or the Museum of Modern Art in New York, the soil science texts would surely become best sellers the day after the opening reception!

Never stop dreaming...

Atterberg Limits

Thomas Baumgartl

Institute for Plant Nutrition and Soil Science, Kiel University, Kiel, Germany

Abstract

Soil is exposed to different states of stability depending on the amount of water that it contains. This characteristic is described as consistency and specifies the state of a remolded and cohesive soil in the range from the liquid (when wet) to plastic and finally solid (when dry) state. Different soils contain a specific amount of water at these different states of stability. In 1911, the Swedish soil physicist Atterberg developed a classification system and method with which these states of consistency could be determined. The method is based on the determination of the water content [calculated as: (mass of water)/(dry mass of soil)] at distinct transitions between different states of consistency of soil. These transitions are defined as liquid limit, plastic limit, and shrinkage limit and are generally referred to as Atterberg limits. The values for these limits are dependent on various soil parameters, e.g., particle size, specific surface area of the particles which is able to take up water, and hence its particle size distribution. These limits are used to derive indexes, e.g., index of plasticity and index of consistency, and are often used for the mechanical characterization of soils.

DEFINITION OF LIMITS AND THEIR DETERMINATION

Liquid Limit (Upper Plastic Limit; w_L)

The liquid limit describes the transition from a viscous liquid to a plastic state. Soils with a water content at the liquid limit barely flow under an applied force. The associated capillary forces of the water menisci in the unsaturated pore system are equivalent to $pF \sim 0.5$ (~ 0.3 kPa matric potential).^[1]

The liquid limit is determined by a method and device developed by Casagrande. The principle is to find the water content (kg/kg) at which a soil sample starts to liquefy under a small applied stress. In practice, a groove is cut into soil samples with different water contents.

These soil samples are then exposed to a small standardized force by repeatedly dropping the Casagrande cup over a distance of 10 mm until the groove is close to ca. 10 mm. A semilogarithmic plot of the number of blows as a function of water content will result in a straight line. The liquid limit is defined as the water content at 25 blows (Fig. 1).

Plastic Limit (Lower Plastic Limit; w_P)

The plastic limit determines the transition from a plastic (cohesive) to a semirigid or brittle state. Under an applied force cracking will occur. In sandy soils, the plastic limit often cannot be determined. The matric potential at the plastic limit is the main cohesive stress and ranges between 63 and 200 kPa (pF 2.8–3.3).^[1]

The plastic limit is determined by forming a moist ball from 2 to 3 g of soil, which is then rolled on—a piece of frosted glass to a rod of thickness ca. 3 mm. The remolding and rolling are repeated until the 3 mm rod starts to break up into pieces of 10–20 mm. The gravimetric water content (kg/kg) at this point gives the plastic limit.

Shrinkage Limit (w_S)

Cohesive and remolded soils reduce their soil volume with the loss of water due to capillary forces. If in a drying process the reduction of the total soil volume equals the volume of water loss, then the soil shows normal shrinkage. Below a certain water content, the further shrinkage of the soil volume is restricted due to a high number of particle contact points and high effective stresses. This restricted shrinkage pattern is called residual shrinkage (Fig. 2). The transition from normal to residual shrinkage defines the shrinkage limit.

The shrinkage limit is often calculated by the following formula:

$$w_S = 0.65 \times w_P \quad (1)$$

Index of Plasticity (I_P)

The I_P is the amount of water between plastic and liquid limit and is calculated by the following formula:

$$I_P = w_L - w_P \quad (2)$$

It describes the sensitivity in the mechanical behavior of a soil toward changes in water content. However, it does not explain mechanical stability, as hydraulic parameters

Fig. 1 The determination of liquid limit.

are not included which are necessary as water flow becomes important when stresses are applied on a soil sample. Values for the index may range from 0 (no plastic behavior) for sandy material to 1 (100%) for clay.

Index of Consistency (I_C)

The I_C is determined as the ratio of the difference between the liquid limit and actual water content and the I_p as follows:

$$I_C = \frac{w_L - w}{w_L - w_P} = \frac{w_L - w}{I_p} \quad (3)$$

Fig. 2 Shrinkage behavior with change in water content in relation to Atterberg limits w_S , w_P , w_L , and Atterberg indexes.

Source: From Kretschmer.^[3]

The water content was such provides no information about the consistency of soils. The same water content in a sandy soil may reflect a liquid state, whereas in a clay soil the behavior may be brittle. The I_C normalizes the water contents and characterizes whether the soil is close to the plastic limit ($\max I_C = 1$) or the liquid limit ($\min I_C = 0$).

Index of Shrinkage (I_{Sch})

The difference between the plastic limit and the shrinkage limit results in the I_{Sch} by the following formula:

$$I_{Sch} = w_P - w_S \quad (4)$$

Soils with water contents within this range are most suitable for cultivation (see Fig. 2). Table 1 summarizes some general values for the Atterberg limits and indexes.^[2]

FACTORS INFLUENCING THE ATTERBERG LIMITS

Many mechanical processes are linked to hydrological properties of soils. Therefore, values of the limits and indexes are influenced by factors, which are generally important for the water retention curve, e.g., the capacity of swelling and shrinkage, clay content, type of clay minerals, and organic matter.

Generally, the values of the limits and indexes increase with their clay content. As the liquid limit increases in comparison to the plastic limit, the I_p also increases. The swelling and shrinkage intensity are dependent not only on the amount but also on the type of clay mineral. Skempton introduced the following factor described as the activity of clay:^[3,4]

$$A = \frac{I_p}{\% \text{ clay content}} \quad (5)$$

The values of A can be classified as follows: 1) $A > 1.25$: active soil with high capacity of swelling and shrinking [calcium montmorillonite ($A \sim 1.5$), sodium (Na) montmorillonite ($A \sim 7.5$), smectite, and salt influenced clays]; 2) $0.75 < A < 1.25$: normal soils (illite); and 3) $A < 0.75$: inactive clay with only little swelling–shrinking activity (kaolinite).

Table 1 Consistency limits (g water/g soil) for different soil textures.

Texture	Sand	Silt	Clay
Consistency limits			
Liquid limit	0.15–0.20	0.30–0.40	0.40–1.50
Plastic limit	0	0.20–0.25	0.25–0.5
I_p	0	0.10–0.15	0.10–1.00
Shrinkage limit	0.12–0.18	0.14–0.25	0.08–0.25

Source: From Kezdi.^[2]

Organic matter increases both the plastic and liquid limits but does not have a big effect on the I_P . Organic substances in a soil matrix seem therefore to increase the surface hydration. Once this pool for water uptake is saturated, the soil shows the same mechanical behavior toward changes in water content as when organic matter is absent, only at a higher level of water content. Thus, the I_C is higher.^[1]

With the exception of organic matter and clays, the amount and type of exchangeable cations have a significant effect on the value of the limits.^[5–7] Na-saturated soils reduce the liquid limit but increase the shrinkage limit. Soils therefore have the tendency to show crust formation at an earlier stage and will slake at lower water contents.^[1,2]

APPLICATION

Soil characteristics are inherent in the values of the Atterberg limits. Therefore, Atterberg limits are correlated with soil properties. For specific soils, investigations have been carried out which correlate the total particle surface with the plastic limit.^[8,9] Soil strength can be defined by its compressibility, and compressibility is correlated to the Atterberg limits.^[10] As soil strength is influenced to a great extent by the energy status of the capillary water, Atterberg limits reflect the soil water potential and show the dependency on texture and the water retention curve.^[11]

At a broader scale, the Atterberg limits can be used for the evaluation of the trafficability and cultivation of soils. Table 2 lists the limits and derived mechanical properties and qualities of soil substrates.

From this classification (Table 2), it is evident that an optimal range of water contents for agricultural use can be determined. This range is present when the soil is stiff and has a compression strength of >100 kPa and an I_C between 0.75 and 1. Drier soils increase the energy input needed for cultivation, which can be a serious problem for clay-rich soils as plowing can become difficult. In the case of lower than optimal plasticity indexes, the soil structure can be destroyed easily when the soil is kneaded by trafficking resulting in ecological problems. As a result, the hydraulic conductivity and gas flow as well as nutrient uptake of plants can be reduced. Hence, cultivation at I_C smaller than

Fig. 3 The classification of soils according to Atterberg limits and Casagrande A-line.

0.75 can have a serious effect on plant growth and soil biological activity.

Although the values of the limits and indexes are not independent values, they can be related to each other (e.g., I_P and w_L). Classifications with respect to particle size distribution, geological origin of material, and suitability under soil mechanical point of view can be derived thereafter. With the ratio of liquid limit and I_P , a linear relationship was found by Casagrande and described as A-line,^[12] following the equation:

$$I_P = 0.73(w_L - 0.2) \quad (6)$$

It distinguishes soil with content of organic matter of $<5\%$ above this line from those in the range of 5–30% below the line. Certain groups of soils and soil substrates can be classified as shown in Fig. 3.

Soil mechanical parameters including the angle of internal friction and cohesion (the principle parameters for defining soil mechanical stability) can be related to the Atterberg limits as well.^[13,14] Generally, the angle of internal friction increases with decreasing soil substrate

Table 2 Mechanical properties of soils and Atterberg limits.

I_C	0	0.25	0.5	0.75	1	1.3	
Symbol	w _L				w _P	w _S	
Index			I _P			I _{Sch}	
Description	Slurry	Very soft	Soft	Deformable	Stiff	Medium hard	Hard

plasticity, i.e., with decreasing liquid limits. Cohesion increases with increasing I_p ; however, the increase is less with decreasing plasticities (see Table 3).

LIMITATIONS

Atterberg limits are empirical values developed for engineering purposes. They describe in approximation the change of the properties of soil material. The limits reflect not a sudden change in the mechanical state of soils but rather transitions. The determination of the limits does not describe processes but only categories for the classification of the soil. As denoted, capillary forces, tensile stresses, and volume change due to external and internal stresses are the parameters that determine the material behavior of the soil substrates. The determination of the Atterberg limits requires the destruction of structural units within the soil and remolding. Usually structure formation increases the strength of soils mainly by reorientation of particles and formation of bonding between particles. The interpretation of the Atterberg limits under agricultural–technical aspects should take these considerations into account.

University Park, Pennsylvania, U.S.A.

Abstract

Bacteria are the most numerous microorganisms in soil, comprising billions per gram of topsoil but decreasing quickly with soil depth (to hundreds of thousands per gram). Bacteria make up an important living fraction of soil organic matter. Densities of bacteria are greater in soil associated with plant roots than in soil unaffected by plants. Bacteria use sugars and organic acids released by plant roots as carbon and energy sources. Some bacteria produce growth factors and other stimulatory compounds that improve plant growth and reduce stress. Working in concert with soil fungi, aerobic bacteria decompose organic matter, consume oxygen, build cell material, and respire carbon dioxide. During decomposition, chemical bonds in organic macromolecules are broken, and inorganic nutrients like ammonium and hydrogen phosphates become available for plant uptake. Active bacteria produce extracellular polysaccharides that help bind soil mineral grains into microaggregates. These in turn combine to form macroaggregates in well-structured soils having many macropores. Thousands of bacterial species coexist in soil, and the vast majority are beneficial rather than disease-causing. Specific functional groups of soil bacteria are responsible for key transformations of nitrogen (N), including atmospheric dinitrogen fixation, N mineralization, nitrification, and denitrification. Soil pH is an important factor influencing bacterial community composition.

INTRODUCTION

Soils contain a myriad of microscopic organisms belonging to all three domains of life (*Bacteria*, *Archaea*, and *Eukarya*), but bacteria are the most numerous. A single gram of garden soil may contain billions of individual bacteria coexisting with millions of archaea and thousands of Eukarya. *Bacteria* and *Archaea* are prokaryotic (i.e., single cells with nuclei that are not membrane-bound), while *Eukarya* are eukaryotic (i.e., single-celled or multicellular organisms having membrane-bound nuclei and other organelles). Among *Eukarya*, soil-dwelling taxa include protozoans and fungi, which themselves serve as hosts for bacteria inside or outside their cells.

As the most numerous microorganisms in soils, bacteria are important drivers of terrestrial carbon (C) and nitrogen (N) cycling. Soil bacteria act in concert with fungi in decomposing plant, animal, and microbial residues to obtain C and energy for growth (chemoheterotrophy), and their organic degradation products speed rock weathering and clay formation during soil development. The bacteria responsible for most organic matter decomposition in soils are aerobic chemoheterotrophs [i.e., they respire oxygen (O₂) to break chemical bonds in organic compounds to obtain energy and C]. Such nutrients as ammonium (NH₄⁺) and phosphate (H₂PO₄⁻), contained within plant litter as it enters the soil, cannot be taken up by plant roots until decomposer bacteria and fungi break the

organic–inorganic chemical bonds. Recycling of nutrients to support primary production and plant growth is therefore a crucial function of soil bacteria. Although aerobic heterotrophs make up a large fraction of soil bacterial communities, other bacteria with diverse physiologies also abound in soils.

This entry gives an overview of how our understanding of bacterial life has advanced over the years, from the use of microscopy and the study of pure cultures to Carl Woese's pivotal discovery of three domains of life based on ribosomal ribonucleic acid (rRNA). Since that discovery, the application of deoxyribonucleic acid (DNA)- and RNA-based methods has revealed the existence of many bacterial taxa (genetically related groups) in soils that have never been cultured in the laboratory. This entry describes characteristics and functions of the major phyla of bacteria found in soils and how their spatial distribution and activities are affected by edaphic (soil-related) factors. This entry also describes how DNA sequencing analyses of soil microbial genomes (extant genes) and transcriptomes (expressed genes) are helping to elucidate relationships between soil bacterial community compositions and biogeochemical functions. These functions include diverse transformations of C, N, and pollutants affecting bioavailability and turnover, greenhouse gas fluxes, and ecological interactions influencing plant health and agricultural productivity.

HISTORICAL ADVANCES

Classical Microbiology

Bacteria viewed under the microscope range in size from 0.2 to 1 μm , with most appearing as round (coccus) or rod-shaped (bacillus) cells in singles, doublets, clusters, or chains.^[1,2] Similarity in physical appearance of bacteria, however, masks astounding variety in genetic compositions, biochemical capabilities, and evolutionary histories. In surface soils having favorable conditions of moisture, aeration, organic matter, and other nutrients, bacterial densities can reach up to 10^{10} cells per gram.^[3] Soil bacteria are principal subjects of study in the field of soil microbiology, defined as “the branch of soil science concerned with soil-inhabiting microorganisms, their functions, and activities.”^[4]

Two historical developments made learning about bacteria in soils possible: the microscope developed by Antonie van Leeuwenhoek (1632–1723) and laboratory culture methods developed by Louis Pasteur (1822–1895) and Robert Koch (1843–1910). Culturing methods required sterile growth media and aseptic handling procedures to exclude other contaminating microorganisms and enable the study of genetically pure strains of bacteria.^[1] Such advances opened the way for extensive research on pure and mixed cultures by pioneers Sergei Winogradsky (1856–1953), the Father of Soil Microbiology, and Martinus Beijerinck (1851–1931), known as the Father of Microbial Ecology.^[5]

Sergei Winogradsky elucidated many different biochemical processes performed by bacteria in soils. He demonstrated chemolithotrophic sulfur oxidation, autotrophic nitrification, and N_2 fixation, respectively, at the University of Strasburg, Swiss Polytechnic Institute, and Imperial State Institute in St. Petersburg.^[6] Students learn about bacterial physiologies by creating biochemical gradients and observing bacterial growth in Winogradsky columns.^[1] Martinus Beijerinck, from the Delft School of Microbiology in the Netherlands, isolated cultures of bacteria that could fix atmospheric N_2 either symbiotically in association with plant roots (e.g., *Rhizobium*) or as free-living organisms in the soil (e.g., *Azotobacter*). Robert Koch’s advances in culturing pathogenic (disease-causing) bacteria enabled the study of many other bacteria from the environment.^[1]

Culture-Based Microbiology

Robert Koch’s techniques for isolating pathogens first involved placing infectious material on the cut surfaces of potatoes or solidified gelatin, which were nearly sterile (free of other living organisms) when handled aseptically. These substrates often became liquefied as the bacteria multiplied, causing growth to become mixed and making purification difficult. Subsequently, bacteria were grown in petri dishes containing gels made with agar, a less degradable carbohydrate made from seaweed, enabling outgrowth and multiplication of individual cells into well-separated

colonies (i.e., visible masses of bacterial clones arising from an individual cell). The repeated process of transferring growth from a well-isolated “colony-forming unit” for distribution on fresh sterile medium (serial transfer) is required to obtain cultures that appear genetically pure on microscopic examination.

Pure culture isolation was important in the formulation of Koch’s postulates for confirming that specific microorganisms (e.g., *Mycobacterium tuberculosis*) caused infectious disease.^[1] Successful pathogen control achieved through the study of pure cultures led to an emphasis during the 20th century on the isolation and study of bacteria from environmental samples. During that time, bacterial taxonomy (classification) was based on phenotypic (observable) characteristics, such as cell size and shape, growth characteristics, and basic metabolisms (e.g., aerobic, anaerobic, autotrophic, chemoheterotrophic, chemolithotrophic, and phototrophic).^[1] One particularly useful phenotypic trait is cell wall structure, as demonstrated by either purple or pink coloration of cells viewed under the microscope after Gram-staining. Cell walls of gram-positive bacteria (purple color) have a single, thick layer of peptidoglycan (amino-sugar polymer), while cell walls of gram-negative bacteria (pink color) have a thin layer of peptidoglycan surrounded by a periplasmic space and an outer cell membrane of lipopolysaccharide.^[1,5] Both types of bacteria make up important fractions of soil microbial communities.

Classification of bacterial isolates based on phenotype was difficult and often contradictory. Recognition also arose early in the 20th century that the study of cultured bacterial isolates would yield only an incomplete picture of soil microbial diversity.^[7] When soil smears were examined under the microscope, as many as 100 times more cells could be observed per gram than the number of colony-forming units calculated after dilution and plate counting.^[8] Discrepancies between plate counts and microscopic observations were at first attributed to dead and injured cells. Subsequent use of fluorescent stains^[9] to distinguish live cells from dead cells under the microscope indicated high proportions of viable, but nonculturable bacteria in many environments, including soils.^[8,10] Some unculturable bacteria may actually require unknown, alternative growth conditions (e.g., trace elements, ionic strength, and oxidation–reduction status) or substrates produced by different microorganisms (i.e., syntrophs). Some bacteria may undergo cell alteration to form dormant structures (e.g., spores and cysts),^[11] while others may be inactive for long periods interspersed with pulses of activity.^[11] Therefore, the number of detectable bacterial taxa at any given time in soil may far exceed the number of active taxa.^[12]

Process-Based Microbiology

Recognition that culture-based methods did not recover all microorganisms from soils led to a greater focus during the

1960s–1990s on measuring end products of collective processes carried out by whole soil microbial communities (i.e., a “black box” approach to soil microbiology).^[13] Aerobic respiration, e.g., is a key C cycling process whereby microorganisms generate energy from the oxidation of reduced C compounds (electron donors) to carbon dioxide (CO₂) and using the electrons to reduce the electron acceptor (O₂) to H₂O. Aerobic respiration by soil communities is thus measured as CO₂ emission rates and is directly related to C mineralization. Net C mineralization rates (micrograms of C–CO₂ per gram of soil⁻¹ d⁻¹) may be measured in the field or under optimized, controlled conditions in soil mesocosms in the laboratory (to estimate “potential” rates).^[11,14] Soil respiration rates following addition of labile C (e.g., glucose) to soils (substrate-induced respiration assays) also are used to determine the size of the soil microbial biomass. Group-selective antibiotics (i.e., cycloheximide to inhibit fungi or streptomycin to inhibit bacteria)^[11] permit estimation of the relative contributions by bacteria and fungi, respectively, to respiration. Gas fluxes from sterilized soils also are measured to rule out effects due to abiotic factors.

Bacterial respiration can also occur in the absence of O₂, such as when soils become anoxic upon water saturation.^[5] Under these conditions, facultative anaerobic bacteria (capable of growing in the presence or absence of O₂) can transfer electrons from C substrates to such acceptors as nitrate (NO₃⁻), ferric iron (Fe³⁺), or sulfate (SO₄⁻). Anaerobic respiration can be tracked by measuring concentrations of oxidized or reduced forms of these electron acceptors coupled to CO₂ emission. Other process measurements related to C cycling include fermentation (use of partially oxidized organic compounds as sources of energy) and methane production and consumption.^[1,3] Measurements of N cycling processes include ¹⁵N isotope tracing to measure N₂ fixation to intracellular amino-nitrogen, N mineralization (net production of NH₄⁺ and NO₃⁻ during decomposition of organic matter), nitrification [oxidation of ammonia (NH₃) to NO₂⁻ and NO₃⁻],^[13] and denitrification (reduction of NO₃⁻ or NO₂⁻ to N₂ or the trace gas nitrous oxide).^[15] Chromatographic and mass spectrometric instruments, which provide fast and accurate measurements of specific compounds, also are used to track end products of degradation processes.^[3]

In lieu of culturing or microscopic enumeration, total soil microbial biomass content can be estimated by extracting and measuring certain chemical compounds from whole soils. Extraction of microbial phospholipids is one such approach, while measuring changes in extractable C before and after fumigating soils with chloroform is another.^[3] As a rule, soil microbial biomass is directly proportional to soil organic matter (SOM) content, making up about 1% of total soil organic C. Since stable SOM is estimated to contain 58% organic C,^[16] a soil containing 3.5% organic matter, e.g., would have about 20 g organic C kg⁻¹ and 0.2 g microbial biomass C kg⁻¹ soil. Increasing SOM content by amending soils with cover crop residues,

animal manures, or composts, e.g., is the most direct way to increase microbial biomass in agricultural soils.^[5]

Molecular (DNA-Based and RNA-Based) Microbiology

A universal classification system for bacteria arose during the 1970s–1980s from the work of Carl Woese, who collected as many pure cultures as possible to compare their genetic variations.^[17] Woese based his phylogenetic (evolutionary) tree on sequence variations in the rRNA strands found in ribosomes, the protein-synthesizing components of living cells.^[1] These rRNAs (and the corresponding rRNA genes that encode them on chromosomes) are useful as “molecular clocks” because they are universal (i.e., found in all organisms) and highly conserved (slow to change over time because they are essential to cell survival). Among the different rRNAs found in prokaryotic ribosomes, the 16S rRNA in the small ribosomal subunit has a convenient length for sequence alignments and comparisons (e.g., about 1540 nucleotides in the reference bacterium, *Escherichia coli*). In eukaryotes, the corresponding rRNA is encoded by the 18S rRNA gene (e.g., 1800–1900 base pairs).^[1] Woese’s phylogenetic tree showed how organisms formerly thought to be bacteria (e.g., methane-producing methanogens) are actually archaea, belonging to a domain that is as genetically distinct from bacteria as it is from animals and other eukaryotes.^[17]

DNA-Based Classification of Cultured Isolates

Today, classifying pure cultures of bacteria requires determining the nucleotide sequences of their 16S rRNA genes. This is done readily with polymerase chain reaction (PCR) amplification of genomic (chromosomal) DNA with rRNA-gene-specific oligonucleotide primers.^[1] Resulting sequences are then compared to others (i.e., accessions) in Internet-accessible databases, which are searched for highest nucleotide identities using computer algorithms like Basic Local Alignment Search Tool.^[18] Public databases include GenBank, maintained by the National Center for Biotechnology Information of the U.S. National Institutes of Health,^[19] the Ribosomal Database Project,^[20] and the European Nucleotide Archive (in Data Library for the European Molecular Biology Laboratory, <http://www.embl.de/>).

When a nearly full-length 16S rRNA gene sequence of a new isolate is found to have >98% nucleotide identity to that of an accession from a described culture, the two are considered to belong to the same species.^[21] Two isolates with 100% identical 16S rRNA sequences may represent distinctive genomic variants or strains within a species due to genomic variations outside of the 16S rRNA gene. (Species are defined as having 70% genome sequence identity.^[22]) In many searches, new DNA sequences exhibit low nucleotide identities to database accessions. Recognized taxonomic thresholds for 16S rRNA nucleotide identities are 94.5% for genus, 86.5% for family, 82% for order, 75.5% for class, and

75% for phylum.^[21] Within the domain *Bacteria*, a total of 89 phyla are recognized. This total includes 29 established phyla having cultured representatives and 60 candidate phyla, known to exist based on recovered DNA sequences but not represented by cultured isolates.^[22] It should be noted that the definition of a bacterial phylum is subjective and that classification systems are subject to change as new accessions are continually added to public databases (several hundred thousand sequences annually).^[21]

DNA-Based Characterization of Communities Without Culturing

In addition to their use in classifying cultured isolates, DNA-based methods enable characterization of microbial community composition in environmental samples without culturing.^[12] Such cultivation-independent methods involve analysis of mixtures of microbial DNA (i.e., metagenomes) extracted directly from a sample after lysing the indigenous organisms by chemical or physical breakage.^[23] Torsvik, Daae, and Goksoyr, at the University of Bergen, Norway, were the first to analyze whole DNA extracts to assess bacterial richness (numbers of different species) in soils. They measured reannealing rates of DNA mixtures to estimate that 1 g of forest soil harbored 4000–10,000 different bacterial genomes.^[24] Following this pioneering insight, many studies employed PCR amplification to prepare 16S rRNA clone libraries from extracts of soil microbial community DNA.^[12] Subsequent development of next-generation (automated, high-throughput) DNA sequencing technologies allowed generation of massive numbers of rRNA gene amplicons (e.g., 2000–20,000 short sequences, or reads, per soil sample).

Increasingly, rRNA gene sequences have been used to characterize soil microbial diversity on the basis of “operational taxonomic units” (OTUs), rather than species. Typically, 16S rRNA gene sequences that are 97–98% similar to each other are grouped within an OTU.^[25] Whereas soil bacterial richness refers to the number of different OTUs detected in a specified volume of soil, diversity indices take into account richness as well as relative abundances of sequences in different OTUs. Widespread and reproducible recovery of identical 16S rRNA gene sequences from diverse soils revealed the existence of uncultured bacteria representing candidate phyla in the bacterial phylogenetic tree.^[21,22] The application of high-throughput sequencing studies has enabled better understanding of the biogeography of soil bacteria^[26–28] and how soil bacterial diversity varies with scale.^[29]

Analyzing DNA or RNA provides different types of information about community composition. At any given time of soil sampling, most bacteria are *metabolically inactive* because of nutrient limitation. DNA-derived sequences thus represent bacterial taxa that are *present* in soils, while RNA-derived sequences provide better coverage of *actively transcribing* taxa, which tend to have higher ribosomal

contents per cell.^[1] Soil RNA extracts contain both rRNAs and messenger RNAs (representing functional gene transcripts prior to their translation into proteins). Extracted RNAs can be reverse-transcribed to generate copy DNAs from a metatranscriptome that represents genes being *expressed* at the time of soil sampling.^[1] Even without culturing, therefore, information about physiologies and metabolisms of extant members of candidate phyla can be obtained. Targeted high-throughput sequencing yields large numbers of amplicons from specific genes, while “whole genome shotgun” (WGS) sequencing yields short reads from whole genome mixtures. Short DNA reads (50–250 bp) can be computer-assembled into longer, contiguous fragments of genomes and sorted with bioinformatics tools.^[28] Classifications based on 16S rRNA genes may be modified using identities of housekeeping genes (which code for proteins with essential functions) or whole genomes.

Bacterial Diversity in Soils

Soil bacterial communities are composed of diverse species belonging to a wide range of phyla. Table 1 lists phyla reported in two extensive reviews of soil bacterial diversity and the percentages of total reads determined for each phylum in these two studies.^[7,28] Five established phyla were ubiquitous and abundant in soils (>5% of rRNA gene reads): *Proteobacteria*, *Acidobacteria*, *Actinobacteria*, *Bacteroidetes*, and *Verrucomicrobia*. Five established phyla were ubiquitous but less abundant (1–5% of reads): *Firmicutes*, *Planctomycetes*, *Chloroflexi*, *Gemmatimonadetes*, and *Cyanobacteria*. Other established phyla that were consistently detected but present at even lower percentages (<0.5%) were *Nitrospirae*, *Thermi*, *Chlorobi*, *Fibrobacteres*, as well as the candidate phyla OP11 and TM7. Bacterial taxa present at <0.5% are described as belonging to the “rare biosphere” and may exhibit distinctive growth responses in soils.^[11]

In general, only about 1% of soil microbial community DNA is typically derived from the *Archaea*, which have cell membranes and wall structures distinct from *Bacteria*.^[1,22] Fundamental knowledge about the physiological characteristics of pure cultures in established phyla is described in the multivolume resource, *Bergey's Manual of Systematic Bacteriology*.^[30–34] Table 1 cites the *Bergey's* volume containing relevant information about each phylum. Even without culturing, however, the increased use of WGS sequencing of environmental DNA is yielding important insights about unculturable organisms in such candidate phyla as TM7 and OP11 (Table 1). These taxa have small cell sizes (<0.2 micron), small genomes, and unusual ribosome compositions.^[35] Genome databases such as Genomes on Line Database^[36] and Genomic Encyclopedia of Bacteria and Archaea are yielding useful insights into how members of all phyla contribute to soil processes and life on Earth.^[22]

Of the 10 most abundant, established bacterial phyla found in soils, only 4 are readily culturable and represented by large numbers of isolates: *Proteobacteria*,

Table 1 Major bacterial phyla detected by their 16S rRNA genes in DNA extracts from surface soils

Phylum	Average (range) ^[7]	Average (range) ^[28]	Subgroups found in soils and examples of known characteristics and functions (list is not exhaustive)
Proteobacteria ^[30] well-represented by cultured isolates, but many remain uncultured	39 (10–77)	20 (6–31)	Gram-negative cell walls; four classes are abundant in soils (no <i>Epsilonproteobacteria</i>)
	19	9 (1–15)	<i>Alphaproteobacteria</i> [fix N ₂ ; endophytes; prey on bacteria; oxidize nitrite; oxidize methane (CH ₄)]
	11	4 (1–11)	<i>Betaproteobacteria</i> [fix N ₂ ; oxidize ammonia (NH ₃), denitrify; prey on bacteria; oxidize CH ₄]
	8	3 (1–10)	<i>Gammaproteobacteria</i> (denitrify; ammonify nitrite; plant pathogens; solubilize phosphate)
	3	3 (0.1–11)	<i>Deltaproteobacteria</i> (many anaerobes; reduce sulfate; prey on other bacteria)
Acidobacteria ^[31] Subdivision 1 members are readily cultured	20 (5–46)	20 (0.1–46)	Gram-negative cell walls; comprise at least eight subgroups, few cultured representatives; Subgroups 1, 4, and 6 most abundant in soils, with Subgroup 3 (<i>Solibacteres</i>) abundant in some soils; all aerobic except for Subgroup 8
Actinobacteria ^[32] (formerly called “actinomycetes”)	13 (0–34)	14 (2–41)	Gram-positive cell walls; filamentous or pleomorphic morphologies; three subgroups common in soil: <i>Actinobacteridae</i> (most abundant, many cultured, aerobic heterotrophs, produce antibiotics); <i>Acidimicrobidae</i> (few cultured, include acidophiles that oxidize ferrous iron); <i>Rubrobacteridae</i> (few cultured aerobic heterotrophs, possibly other physiologies)
Verrucomicrobia ^[31]	7 (0–21)	13 (0.2–40)	Five major classes; Class 2, <i>Spartobacteria</i> most common, aerobic heterotrophs, some are nematode symbionts; many uncultured members with unknown physiologies
Bacteroidetes ^[31] (CFB group)	5 (0–18)	11 (2–40)	Gram-negative cell walls; of four subgroups, three common in soil: <i>Sphingobacteria</i> most common (aerobes, anaerobes, or facultative; degrade chitin); <i>Flavobacteriia</i> (aerobic heterotrophs); <i>Cytophagia</i> (aerobic heterotrophs, degrade cellulose); <i>Bacteroidetes</i> (uncommon, but may be symbionts or commensals in soil fauna)
Chloroflexi ^[33]	3 (0–16)	2 (0.6–3)	Phylum may be as diverse as Proteobacteria; possibly eight major subgroups; only one isolate from soil (aerobic heterotroph)
Planctomycetes ^[31]	2 (0–8)	2 (0.1–4)	Lack cell walls; budding morphology; may possess intracellular, membrane-bound compartments; two major subgroups: Phycisphaerae (rhizosphere) and Planctomycetia (includes soil isolates; anammox bacteria that oxidize NH ₃ anaerobically)
Firmicutes ^[34]	2 (0–8)	0.5 (04)	Gram-positive cell walls; form heat-resistant spores; two major subgroups: <i>Bacilli</i> (readily cultured aerobically; lactic fermenters) and <i>Clostridia</i> (anaerobes)
Gemmatimonadetes ^[31]	2 (0–4)	2 (0.1–4)	Gram-negative cell wall; aerobic heterotrophs; one major group; few cultured; little known physiologies
Cyanobacteria ^[33]	< 1	3 (0–25)	Photosynthetic; fix N ₂ ; unicellular, colonial or filamentous morphologies; Gram-negative cell walls; may form biofilms on soil surfaces; symbiotic partners with fungi in lichens

Following “low-abundance” phyla are cosmopolitan but detected at frequencies of < 0.5% of DNA/RNA reads; also called “rare phyla”^[11,27]

Nitrospirae ^[33]	Includes <i>Nitrospira</i> spp. that oxidize nitrite and <i>Leptospirillum</i> spp. that oxidize ferrous iron for energy
Deinococcus-Thermi ^[33]	Includes radiation-resistant, thermophilic members; physiologies and functions in soil unknown
Chlorobi ^[33]	“Green sulfur bacteria” anaerobic photoautotrophs that oxidize sulfide or sulfur; physiologies and functions in soil unknown
Fibrobacteres ^[31]	Anaerobic, some chitinolytic, includes termite-gut inhabitants
OP11, TM7	Lineages in candidate phyla radiation characterized by small cell size (pass through 0.2-micron filters; small genomes indicative of fermentative physiologies ^[35])
Candidate phyla ^[22]	BRC1, NKB19, OP10, OS-K, SC3, SC4, TM6, WS2, WS3 (no cultured isolates)

Note: CFB, Cytophaga-Flavobacterium-Bacteroides group.

Actinobacteria, *Bacteroidetes*, and *Firmicutes* (Table 1).^[7] In soils, readily cultured bacteria are described as having “r-selected” growth strategies. Such organisms compete well for available C, grow quickly under high-nutrient (copiotrophic) conditions, and decline rapidly when nutrients are depleted.^[36] Members of the less readily cultured phyla, such as *Acidobacteria* and *Verrucomicrobia*, may therefore have “k-selected” lifestyles characterized by slower growth and better adaptation to low-nutrient (oligotrophic) conditions. Despite few cultured isolates, the phylum *Acidobacteria* is composed of as many as eight major classes,^[33,37] possibly encompassing as much phylogenetic breadth as *Proteobacteria*. The latter phylum comprises six major classes (alpha-, beta-, gamma-, delta-, epsilon-, and zeta proteobacteria) with more than 550 recognized genera,^[22,30] ranging from chemolithotrophs using reduced inorganic compounds for energy (e.g., NH_3 oxidizers and hydrogen oxidizers) to obligate symbionts that can only reproduce inside specific host organisms.^[1,30] Despite high physiological diversity observed among cultured *Proteobacteria*, the majority of their DNA sequences in soils belong to taxa that contain no cultured representatives.^[38]

BACTERIAL LIFE IN SOILS

Soil Microenvironment and Ecological Interactions

Bacteria are non-uniformly distributed in soils, being more abundant in surface horizons near plant roots and in zones rich in organic matter.^[3] Bacterial biomass in soil thus tends to reflect organic matter distribution, with bacterial numbers quickly declining with soil depth.^[3,5] Most bacteria live in soils as microcolonies (2–10 cells) tightly attached to surfaces,^[39] rather than as planktonic (free-floating) organisms in soil solution. By producing mucilaginous polysaccharides (i.e., mucigels), bacteria can become enmeshed with clays and organic colloids to initiate soil aggregation.^[3,5] Bacteria adhering to soil surfaces inside pores (Fig. 1) are protected from desiccation and grazing by protozoan and other faunal predators.

Soil bacterial habitats are shaped by soil structure, which is the 3-D arrangement of sand, silt, clay, and organic matter into aggregates and pores.^[16] Optimal bacterial growth conditions are provided by soils with favorable organic matter, water-holding capacity, and aeration, all of which are supplied by well-structured soils with a high proportion of macroaggregates (>250 microns) and macropores (>60 microns).^[16] Macroaggregate formation is hierarchical and biologically facilitated. Inner microaggregates, formed through the binding of clays by bacterial exopolysaccharides, are held together through the action of fungal hyphae and root hairs (Fig. 1). Extensive formation of soil macroaggregates increases macroporosity, thereby enhancing air and water infiltration and positive feedback effects on

Fig. 1 Scale drawing of a typical soil aggregate. Sand (>50 μm), silt (2–50 μm), and clay (<2 μm) particles become cemented together with organic matter and microbial substances as a result of microbial activity. Note the pore in the center of the aggregate and the meniscus of water surrounding the airspace inside the pore. Bacteria are shown as dark rods and filaments (actinomycetes). Fungal filaments (hyphae) surround the aggregate. This illustrates how an aggregate can offer a diverse set of microsites for bacterial habitation over very short distances.

root and microbial activity. Well-aggregated soils may provide more varied niches to support diverse bacterial metabolisms, because large aggregates can exhibit steep gradients in O_2 and redox potential.^[3,5]

Most soil bacteria require external sources of reduced C and N for growth and reproduction.^[1] Cyanobacteria are an exception in that they can use light energy to reduce CO_2 during photosynthesis and tap the resulting photosynthate for energy to reduce (fix) N_2 gas from the atmosphere.^[33,40] Cyanobacteria thus play critical roles as pioneer species on rock surfaces, particularly in symbioses with fungi (as lichens) or in associations with moss mats.^[41,42] The CO_2 respired by pioneer communities dissolves in rainwater to form carbonic acid, which helps solubilize and weather rocks. Essential metal nutrients released during rock weathering can form ligands with other organic acids produced by bacteria and their partners. Organic–metal ligands keep nutrients in solution and bioavailable, and they also serve to initiate formation of colloidal secondary minerals important for soil development.^[42]

Bacteria in soils participate in many diverse ecological interactions: as predators of other bacteria;^[43] as food sources for protozoans; as pathogens, parasites, or antagonists of other organisms (e.g., antibiotic producers); and as plant commensals or symbionts.^[3,44]

Establishment of interactions between bacteria and organisms in higher trophic groups clearly requires that these latter groups be maintained within soil habitats. Compared to quiescent soils under perennial vegetation, soils that undergo regular physical disturbance (e.g., by agricultural tillage)

provide less favorable habitats for larger organisms that are more desiccation-sensitive, thus resulting in less trophic complexity. Perennial vegetation also supplies soils with root exudates for longer periods of time than annual crops, so that greater substrate availability supports greater microbial biomass and activity. Cooperative interactions between bacteria also occur as a result of quorum-sensing chemicals^[44] or the transfer of genes via plasmids.^[45]

Bacterial Functions in Soil-Plant Systems

Even though bacteria have great functional importance in driving biogeochemical cycles, bacteria occupy no more than 0.4% of the total pore space of soils.^[39] Bacterial growth in most soils is limited by soluble C,^[3] although N availability may also influence activity.^[46] Although the bacterium's small size and high surface-to-volume ratio^[1] make it highly efficient in taking up nutrients, its limited mobility renders it dependent on the immediate environment for nutrient supply. It has been estimated that total C inputs from plant litter and root exudates in an agricultural soil may support only four to five bacterial growth cycles per year.^[3] In soils, average bacterial cell size (0.3–0.4 micron) can be less than half that observed for cultured bacteria growing in nutrient-rich medium in the laboratory.^[2,10]

Certain bacterial populations (e.g., in the genera *Pseudomonas* spp. and *Burkholderia* spp. of the *Gamma-proteobacteria* and *Betaproteobacteria*, respectively) are typically 10–100 times more numerous in zones immediately surrounding plant roots (i.e., rhizospheres rich in root-derived nutrients) than in bulk soils (not influenced by roots).^[3,5] Higher microbial densities in rhizosphere soils (soil adhering to excavated roots after physical shaking) relative to bulk soils are described as the rhizosphere effect. Plant roots exude or secrete chemicals that stimulate bacterial movement toward roots by chemotaxis. Root-associated bacteria carry out several functions that can be beneficial to plant nutrition and health, such as H_2PO_4^- mineral solubilization, N_2 fixation, iron chelation, phytohormone production, ethylene suppression, and facilitation of root colonization by mycorrhizal fungi.^[44,47,48]

Soil bacteria may colonize root surfaces or enter the roots through epidermal junctures to become endophytes. Some soilborne bacteria can be pathogenic (disease-causing) to plants (e.g., *Agrobacterium tumefaciens*, which causes crown gall, and *Erwinia carotovora*, which causes soft rots). However, many bacterial pathogens are introduced into soil with infected seeds or other planting materials, and bacteria as a group cause less overall economic damage to crops than pathogenic fungi, protists, or viruses.^[49,50] Some soils exhibiting high biological activity have been characterized as disease-suppressive, due to the action of microbial competitors and antagonists of plant pathogens.

Interest has increased in the possibility of using plant-growth-promoting rhizobacteria as seed or soil inoculants.^[44] High densities of bacteria (e.g., 10^6 viable cells per

milliliter), however, are generally required for efficacy.^[50] Although significant measurable results after inoculation of seeds or roots have been documented under controlled greenhouse conditions, comparable outcomes may not be reproduced in the field due to the great spatial heterogeneity of soils and their management histories.^[47] The ability of viable cells in an inoculated culture to survive and grow in a plant–soil system is dependent on diverse outcomes involving the physicochemical status of the soil and competition or cooperation with resident soil organisms. Inoculants must therefore contend with the entire assemblage of life in a soil, which is sometimes referred to as the “edaphon,” from the Greek word for “ground” or “soil,”^[4] encompassing all other bacteria, archaea, viruses, fungi, protists, nematodes, microarthropods, earthworms, and other soil fauna.

In subsoils below the root zone, bacteria are present but at lower densities (10^3 – 10^5 g^{-1}), and they may survive extended periods of soil nutrient deficit by invoking the following mechanisms: induction of low metabolic rates to reduce energy requirements,^[51] accumulation of intracellular polymers for C storage, production of extracellular polysaccharides to envelope and protect cells from desiccation, release of extracellular enzymes to solubilize nutrients, and formation of spores, cysts, and other resting-state structures.^[1] Some bacteria survive for decades in dried soils.^[5] Our knowledge that thousands of different bacterial species can coexist within 1 cm^3 of soil reflects a high degree of spatial and temporal heterogeneity in soil *micro-niches*, where appropriate conditions for growth may occur only sporadically during the growing season.^[11]

Despite the high complexity and heterogeneity of soil microbial communities, species diversity measures adopted from macroecology can be useful in their characterization; e.g., R. H. Whittaker's^[52] concept of gamma diversity (all species in a landscape encompassing multiple habitats) could be applied to all microbial taxa in a soil unit (e.g., one soil type in an agricultural field, pasture, or forest). Mean alpha diversity measures (species within habitats) could be determined separately for bacterial taxa in rhizospheres, bulk soils in surface horizons, and subsoils, with differences in these taxa used to characterize beta diversity (species differences across different soil habitats) of the soil unit.^[28]

Scientific motivation for understanding soil microbial community composition is based on the need to learn how soil microbiota vary across the landscape, particularly in response to management, and how biotic responses in turn affect ecosystem function and global change.^[53] The most important environmental factor influencing soil bacterial composition appears to be soil pH.^[27,28] Other factors such as vegetation, latitude, soil texture, and organic matter content do not appear to be correlated with total bacterial diversity. In general, neutral soils (pH 6–7) contain much greater bacterial diversity than soils with more extreme pH (<4 and >9). The availability of labile C, however, can influence changes in abundance of taxa associated with

r-selected and k-selected lifestyles. Addition of sucrose to forest soils, e.g., resulted in reproducible increases in *Betaproteobacteria* and *Bacteroidetes* (considered more copiotrophic) and decreases in *Acidobacteria* (more oligotrophic).^[54] Knowledge of how community composition is related to soil function will require integration of DNA sequence analyses with soil process measurements, knowledge of metabolic capabilities, and metadata (information about soils and sampling conditions).^[36]

CONCLUSION

Soils contain billions of bacteria: microscopic, single-celled prokaryotes that carry out diverse processes in nutrient cycling, including organic matter decomposition, secondary production, weathering and mineral nutrient release for plant uptake, and N₂ fixation. Although some bacteria cause diseases of animals and plants, most bacteria are beneficial and absolutely necessary for maintaining the biogeochemical balance of our environment. As technological advances enable more in-depth understanding of bacterial physiologies based on whole genomes, bacterial roles in soils will be more fully elucidated. Integrated approaches will be needed to understand the relationships between soil bacterial community composition and soil function.

Biochar and Soil Characteristics

Atanu Mukherjee

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Biochar is a carbonaceous substance which can be obtained by the process of pyrolysis. Since mid-2000, extensive research on biochar has started and is being carried on because of its intended use as a soil amendment. Although there are uncertainties and concerns about biochar usage under field scale, studies claim improvement in soil quality. This entry outlines impacts of various biochars on selected soil chemical and physical properties, and trends in the results are identified, wherever possible. Selected data from 2010 to 2016 indicate that pH and cation exchange capacity (CEC) of the biochar-amended soils can be increased by up to 73% and 2-folds, with an average of 28% and 30%, respectively, compared to the control. A trend could be established that soil pH can be increased by biochar as amendment but such a trend could not be established with CEC due to conflicting results and lack of field-scale experiments. Data also confirm that higher biochar application rate could be more beneficial toward some soil qualities such as surface area (SA), however, no clear trend has been established. The SA and water-holding capacity (WHC) of the amended soils could be enhanced by up to 5.5- and 1.5-fold, with an average of 2-fold and 31%, respectively, compared to control soils. The WHC of biochar-amended soils is improved under laboratory incubation but not consistently under field studies. A clear trend of decrease in bulk density by up to 24% of the amended soils is observed. Although these data are to be used as representative, however, research priority of biochar amendment studies under field scale and over time is needed to establish trends in soil quality under biochar.

LITERATURE REVIEW

Since the mid-2000s, a number of studies have been done on biochar material itself as well as its effects on soil properties, greenhouse gas (GHG) emissions, and primary productivity, when amended to soil. Biochar is the carbonaceous product of biomass obtained by removing water and other volatile components when plant or animal biomass is subjected to heat treatment. This may occur in the presence of oxygen (hereafter referred to as combustion) or without oxygen (referred to as pyrolysis). However, all biochars are not the same and biochar characteristics mainly depend on the pyrolysis conditions they were made of and biomass types they were derived from.^[1] Thus, when biochars are amended with soils, the resultant soil/biochar mixtures behave differently in properties. This is the primary reason why intensive physical and chemical characterizations of biochar should be made before amending any particular soil type to investigate its effects on the properties of the amended soil. Researchers have made significant progress in understanding biochar's physical and chemical properties and factors such as combustion temperature, heating duration and rate, and biomass species combusted have all been found to influence the properties of biochars produced.

Biochars derived from animal origin (animal bone, poultry or cow manure/litter, and animal waste) are

characteristically different than biochars pyrolyzed from plant biomass.^[2] The key differences are higher phosphorus (P) and other metal availability and pH in the animal-derived biochars than those of plant-derived ones. However, for the plant-derived biochars, generally, lower temperature (<650°C) biochars are characteristically acidic in pH, high in volatile matter and surface functional groups, and low in surface area (SA) and ash content, while higher temperature (>650°C) biochars are usually high in pH, SA, and ash content with low in volatile matter and surface functional groups.^[1] However, some properties of biochar also depend on plant biomass types. The key properties governed by plant biomass types are cation or anion exchange capacities (CEC or AEC), amount of toxic metals, SA, and GHG emissions.^[1,3] A potential biochar should always be amended with the right soil. For an example, an acidic soil should be amended with a biochar with high pH and vice versa. However, due to the lack of consensus, biochar/soil studies have not been designed the way that the outcome becomes most beneficial and lack of field-scale data and the high cost of biochar production have been identified as the constraints of large-scale biochar application.^[4] Noting this in mind, an overview of changes in selected soil chemical and physical properties under biochar amendment is discussed briefly in the following sections based on 2010–2016 data. Although all the soil physicochemical properties are

not given equal attention, an attempt is made to find trends under selected properties.

Biochar Impacts on Soil Chemical Properties

A number of biochar/soil studies demonstrated that biochar can significantly influence amended soils' chemical properties (Table 1). Soil fertility can be improved by biochar addition, reduction of soil acidity, and enhancement of plant-available nutrients. For example, biochars derived from a number of plant and animal origin increased amended soils' pH by up to 73% with an average increase of 28% (Table 1), depending on the application rate.^[5–10] However, although there is conceived knowledge that biochar-amended soil would have higher pH than control soil, it is not always necessarily true. Some biochars (sometimes having pH < 7.0) tend to decrease the pH of the amended soils. For an example, poultry manure biochar pyrolyzed at 300°C decreased pH of amended calcareous soil in a pot study and beech wood biochar produced at 500°C decreased pH of amended loamy silt soil by 1.3% compared to control.^[10,11] However, from the published data, a trend could be drawn that pH of most soils could be increased by biochar addition which is supported by a meta-analysis (n = 146, p < 0.001) indicating that biochar works best in acidic compared to alkaline soil to increase the amended soil's pH.^[12]

The major required soil nutrients for plants are nitrogen (N), P, and potassium (K). Various greenhouse and laboratory experiments exhibited enhancement of soil nutrients level by biochar addition. Biochar also either increased or retained soil nutrients as documented in field and pot experiments.^[11,13] For example, poultry manure biochar pyrolyzed at 300°C decreased the concentration of plant-available iron of the amended calcareous soil but increased plant-available P, zinc, copper, and manganese concentrations and biochar increased the level of exchangeable cations (K, calcium, and magnesium) in the amended soil under a greenhouse pot experiment.^[11] In another field study, compost biochar significantly increased water-soluble N and total and dissolved organic carbon in the amended plots compared to the control calcareous soil in two consecutive years.^[14] Similarly, significant increases of K⁺ and CEC upon the addition of 2.5–10% (w/w) biochar for soils from three regions were observed under corn cob biochar pyrolyzed at 350°C.^[7] Although biochar itself contains nutrients and serves as an adsorbent of the soil nutrients, it also can release nutrients slowly over time and the amount and forms of the nutrients released from biochar depend on biomass type and production temperature of the biochar. For example, biochars derived from a grass type and pyrolyzed at lower temperatures released higher nutrients compared to the biochars derived from woody biomass and pyrolyzed at higher temperatures.^[15]

The extent of nutrient retention or sorption and slow release or leaching over time depends on sorption and the

exchange capacity of biochar/soil mixtures, when amended. The CEC of pure biochar made from diverse biomass sources ranged from 10.0 cmol_c kg⁻¹ to 69.2 cmol_c kg⁻¹ showing an increase in CEC of amended soil by up to 2-folds (Table 1) compared to the control.^[5,7,9,10] However, very few studies documented AEC of biochar-amended soil, which is considered a research priority. On the other hand, very little enhancement or even decadence of CEC by up to 41% (Table 1, negative sign indicates decrease) was also reported in some cases. For example, biochar derived from beech (*Fagus* spp.) and oak (*Quercus* spp.) and pyrolyzed at 500°C, 250°C, and 650°C actually decreased CEC of the amended soils by 7.6%, 25.7%, and 41%, respectively, when amended to loamy silt and forest Spodosols.^[9,10] A biochar derived from poultry litter and pyrolyzed at 450°C decreased the CEC of Frederick silt loam soil under forage and pepper in the first year; however, CEC was increased by up to 9.5% during the second year of the experiment, identifying the importance of biochar field aging,^[16] as aged biochars demonstrate characteristics that significantly improve the soil properties in a longer run as biochar becomes aged over time.^[8,9] Nevertheless, more field-aging studies need to be done focusing on both CEC and AEC of biochar-amended soils, as very few data are available to make any credible interpretations. While a little enhancement of CEC was observed in a number of cases, many times the increment of CEC was not significantly higher compared to the control and thus a clear trend of change in CEC cannot be established.

Biochar Impacts on Soil Physical Properties

While a lot of attention has been given to effects of biochar on soil chemical properties, data are scarce on biochar impacts on soil physical properties, especially under field scale.^[3] Biochars usually are characteristically very light materials with high porosity and SA, which are likely to alter soil physical properties such as bulk density (BD), water-holding capacity (WHC) or available water capacity, SA, and penetration resistance (PR). Only BD and WHC have been investigated in most studies, while a few studies documented SA and PR of biochar-amended soils (Table 1). Although biochars possess high SA, there is a lack of data reported on SA of biochar-amended soils. Increase in SA of the amended soils by up to 5.5-fold (Table 1) has been documented,^[17–19] which indicates advantage of sorption and water/nutrient storage capacity of the biochar-amended soils due to greater extent of SA available for nutrient sorption or storage, when amended. A rate-dependent SA increment trend was noted by at least two different studies. For example, oak and hickory (*Carya* spp.) mixed woods when pyrolyzed at 500°C and mixed with Clarion fine loamy soil increased SA of the amended soil by 3.8% when biochar application rate was increased from 0.5% to 1% (w/w) and jarrah (*Eucalyptus marginata*) woods pyrolyzed at 600°C increased SA of the amended sandy soil dramatically by

Table 1 Changes in soil quality parameters under biochar (numbers in parenthesis indicate average values, and negative sign indicates decrease).

2.1-fold when the biochar application rate was increased from 0.45% to 2.7% (w/w).^[17,18] These data confirm that higher biochar application rate may be more beneficial toward improvement of some soil characteristics such as SA. However, any trend with SA under biochar amendment is to be established without having enough field data and long-term studies.

The BD of the biochar-amended soils is likely to be reduced due to high porosity of the biochars, and a decrease in BD of a range of amended soils was observed by up to 24% (Table 1, negative sign indicates decrease) compared to control soils.^[5,7,19–21] For example, wheat straw derived biochars pyrolyzed at 350–550°C, when amended with variety of soils decreased BD by up to 14% depending on the rate and duration of the experiment.^[20,21] However, significant decrease in BD of the amended soil was not observed in some cases. For example, corn cob biochar pyrolyzed at 350°C was not able to reduce the BD of the amended Mongu soil with 2.5% application rate; however, progressive reduction of BD was observed when application rate increased up to 10% (w/w).^[7] It was concluded earlier that a biochar application rate of 2% (w/w) could be sufficient to reduce the BD of the amended soils,^[3] but the data^[7] indicate more work needs to be carried out on a variety of soil/biochar combinations, especially under field scale. However, despite the complexity of application rates, decrease in BD of amended soils is likely as an observed trend from the data.

On the other hand, many studies indicated that WHC of the biochar-amended soils can be significantly improved by up to 1.5-fold compared to control except for a few cases where WHC of the amended soils decreased to some extent (Table 1). For example, several soil incubation studies indicated that biochars derived from corn stover, oak, and mixed hardwoods enhanced WHC of the resultant soils by up to 33%, 26%, and 20%, respectively, depending on biochar pyrolysis temperatures or application rates.^[7,8,13,19,22,23] A similar response was also observed under field-scale experiments. The amended soils had improved WHC when corn cob biochar pyrolyzed at 350°C applied to three different soil types under conservation tillage system and three application rates (2.5–10%, w/w) with progressive higher WHC observed with a higher application rate,^[7] and a similarly progressive increase in WHC with higher biochar application rate was observed in other studies by Case et al.^[22] and Herath, Camps-Arbestain, and Hedley.^[23] In contrast, a biochar amendment study documented decrease in WHC of the amended soil. Oak biochar pyrolyzed at 650°C decreased WHC of the amended soils by 15% in the first year,^[19] but increased the same by 22% in the second year of the field trial,^[8] although the increment was not significant ($p > 0.05$). These results demonstrate that: 1) the right biochar should be used for the right soil to see the desired benefit; and 2) biochar field aging is important and should be considered in research studies. Additionally, biochar

amendment studies, while aiming for improving soil quality, should have their main goal as increasing crop yield, and significant uncertainties exist at this point.^[4] A meta-analysis (data collected from 23 studies until March 1, 2010) indicates a wide range of outcomes (–28% decrease to +39% yield increase) with a mean yield increase of 10%, and the greatest positive results were observed from acidic to neutral soils with coarse to medium textures indicating liming and improved WHC benefits of soil under biochar.^[24]

SUMMARY

This entry identifies that clear trends under biochar amendment could possibly be established for only pH and BD of the amended soils. Lack of field data on CEC, soil nutrients, aggregation, SA, and WHC is a constraint to validate any trend on these soil attributes. Representative data also indicate that biochar application rate and field aging have significant impacts on improvement of most soil quality parameters. However, the biochar production process is expensive and unless a specific threshold application rate is established, large-scale recommendation is not possible.

Abstract

Biochar is a form of char that is used for environmental applications, principally as a soil amendment or for water treatment. It is produced by the incomplete combustion of biomass and is primarily a mixture of single- and condensed-ring aromatic carbon with lesser amounts of aliphatic carbon, hydrogen, oxygen, nitrogen, and other elements. The addition of biochar to soils returns most of the nutrients that are removed from the soil when biomass is harvested. Biochar has the capacity to retain bioavailable water and is a very strong adsorbent of plant nutrients and dissolved organic compounds. It is an effective soil conditioner that reduces soil bulk density and increases the capacity of soils to retain and supply nutrients and water to growing plants. Because of these positive effects on soil quality, most studies have reported enhanced plant growth for soils amended with biochar; however, caution is urged as biochar quality is critical. Some biochars have the capacity to tie up nutrients whether by immobilization, by nutrient adsorption, or by raising the soil pH to the point that the nutrients are no longer bioavailable.

Biochar, also known as charcoal, black carbon (C), soot, and char, is a broad class of materials produced from the incomplete combustion or pyrolysis of organic materials such as wood, wood by-products, plant residue, manure, petroleum, and petroleum by-products.^[1] Of the terms mentioned, char is the most general and simply implies a particulate pyrogenic (formed by fire) material dominated by a mixture of single- and condensed-ring aromatic C with lesser amounts of aliphatic C, hydrogen (H₂), oxygen (O), nitrogen (N), and other elements. Black C implies a particulate material found in soils and sediments, which resembles char but cannot unequivocally be shown to be pyrogenic. Soot is reserved for char particles that form by condensation from exhaust vapors of open combustion or an internal combustion engine. Charcoal is char that is used as a fuel for cooking or to produce heat. And, biochar is char that is used for environmental applications, principally as a soil amendment or for water treatment.

Biochar has been used as a soil amendment for several thousand years. Extensive regions of Terra Preta de Indio soils in the Amazon basin are Anthrosols made by pre-Columbian Amerindian farmers.^[2,3] In addition to high concentrations of biochar, the Terra Preta soils also contain large amounts of biogenic (formed by living organisms) humic materials and high concentrations of plant nutrients, notably phosphorus (P), which is often deficient in the Oxisols from which the Terra Preta soils were made. Perhaps the most important feature of the Terra Preta soils

is their enhanced capacity to retain and recycle both nutrients and water, and hence their greater fertility and capacity to sustainably support agricultural production relative to the native Oxisols.^[3,4] The pre-Columbian Amerindian farmers of the Amazon are believed to have practiced a form of slash-and-char agriculture whereby they produced and incorporated large quantities of biochar along with fish bones and various organic manures into the native Oxisols in a deliberate attempt to enhance the soil quality. More than 500 years after the cessation of the practices that led to their genesis, the Terra Preta soils are some of the most productive soils of the Amazon and require lower inputs of nutrients for sustainable agricultural and horticultural production compared with the Oxisols from which they were made.

The properties of biochar vary substantially depending on the source of biomass, the rate at which it is heated, the maximum temperature of heating, and the extent to which volatiles produced during pyrolysis are separated from the biochar prior to cooling. The level of aromaticity directly influences the stability of biochar in soil environments. Other properties of biochar that influence soil quality are particle size, porosity, surface area, the density and types of surface functional groups, the concentrations of biologically available and biologically active compounds in the biochar, and the concentrations and forms of inorganic bases that are admixed with the biochar.

During pyrolysis, most plant nutrients in a biomass feedstock are concentrated in the biochar fraction. Inorganic bases, including calcium ions (Ca^{2+}), magnesium ions (Mg^{2+}), and potassium ion (K^+), and most trace elements form oxides and/or hydroxides that are occluded within biochar pores or admixed as discrete particles with the biochar. Approximately, one-half of the N present in the biomass feedstock is partitioned into the biochar during pyrolysis. The other half of the N is volatilized during pyrolysis and then condensed with the bio-oil fraction. Much of the N in biochar is present as heterocyclic N, which adds base functionality to biochar, and is a slowly released source of N fertility in soils. Less is known about the forms and function of sulfur in biochar. Thus, the use of biochar as a soil amendment partially closes the nutrient cycle by returning most of the nutrients that are removed from the soil when biomass is harvested.

The base oxides and hydroxides in biochar are both a source of plant nutrients and a liming agent when the biochar is applied to the soil. Thus, both the fertility contribution and the calcium carbonate equivalent of biochar vary with the concentration of base oxides and hydroxides in the biochar, which primarily depends on the concentration of the bases in the initial biomass feedstock. Base concentrations are typically low in biochars produced from softwoods such as pine, intermediate in biochars produced from hardwoods, and high in biochars produced from grasses and crop residues.^[5]

Freshly made biochar is hydrophobic. On exposure to water and O in soil environments, the surfaces of fresh biochar particles are oxidized leading to the formation of O-containing surface functional groups especially carboxylate and hydroxyl groups.^[6,7] Carboxylate groups are weak acids with pK_a values typically between 4 and 7. Hence in alkaline, neutral, and mildly acidic soils, the carboxylate groups disassociate and produce a negative charge on the surfaces of biochar particles. The high surface area and high density of negative surface charge add cation exchange capacity (CEC) to soils, and together with other polar surface functional groups that form during surface oxidation, the carboxylate groups transform the biochar from hydrophobic to hydrophilic. The rate at which this transformation occurs has not been quantified and will likely depend on other properties of the biochar such as the level of condensed aromatic C and concentrations of O, N,

and other elements that are covalently bound to the aromatic C matrix. Measuring the CEC of fresh biochar is complicated because the CEC is dependent on both pH and the extent of surface oxidation, both of which vary with time after the biochar has been placed in an aqueous solution. Furthermore, the adsorption of both organic and inorganic compounds by biochar in soil environments alters the surface properties of the biochar.^[8] The complexation of polyvalent metal cations by carboxylate and/or other O-containing surface functional groups can transform a surface charge site from negative to positive, effectively creating anion exchange sites. Amphiphilic organic molecules may be adsorbed on biochar particles and oriented with the lipophilic portions of the organic molecules interacting with non-polar regions of the biochar and the polar portions of the organic molecules oriented toward the aqueous phase. Thus, adsorption of organic molecules may contribute additional surface charge to biochar particles and/or alter the hydrophilic–hydrophobic character of surfaces of biochar particles. Because of the processes discussed above, the surface properties of biochar change both with the length of time biochar has been in the soil and with the chemical properties of the soil. Although directly quantifying meaningful properties such as CEC of fresh biochar is difficult, the impact of biochar additions on soil properties can be readily measured after the biochar has had an opportunity to equilibrate with the soil environment. Several studies have measured significantly higher CECs for soils amended with biochar than control soils.^[8,9]

Biochar in various forms is widely used as an adsorbent for removing both inorganic and organic contaminants from wastewater and for purification of drinking water. When mixed with soil, biochar functions in the same way. This is illustrated simply by looking at the color of leachate collected from soil columns following a swine manure amendment (Fig. 1). After the manure amendment, water leaching from the control columns containing soil without biochar was turbid indicating high levels of dissolved organic material, while the water leaching from soil columns amended with as little as 5 g kg^{-1} biochar was nearly clear. The biochar also reduced leaching of nitrate, K^+ , Ca^{2+} , Mg^{2+} , P, and several other nutrients.^[10] Of particular note, leaching of P was reduced by 40–70% relative to the controls, as the rate of biochar amendment increased from 5 to 20 g kg^{-1} . The reductions in nutrient

Fig. 1 Leachate collected from soil columns 2 days after a manure amendment. Column treatments are as follows: C0, no manure and no biochar; C0M, 5 g kg^{-1} manure and no biochar; C1M, 5 g kg^{-1} manure and 5 g kg^{-1} biochar; C2M, 5 g kg^{-1} manure and 10 g kg^{-1} biochar; and C3M, 5 g kg^{-1} manure and 20 g kg^{-1} biochar.

leaching were associated with increases in bioavailable nutrients in the soils measured 500 days after the biochar amendments.^[9] Comparisons of nutrient leaching under Terra Preta soils with adjacent control soils have shown similar nutrient leaching reductions.^[3,4]

Porosity is a key property of biochar (Fig. 2). Some of the pores in the original biologic tissue are preserved in the residual biochar. Furthermore, the desiccation of biologic tissue and the pyrolytic emission of structural water, carbon dioxide (CO₂), carbon monoxide, and H₂ from biologic tissue during pyrolysis create even more internal porosity within biochar particles. Internal porosity lowers the effective particle density and greatly increases the effective surface area of biochar. In soil environments, the low particle density and the high internal porosity of biochar help to reduce the bulk density of soils and increase the capacity of soils to retain bioavailable water, nutrients, and organic molecules, and the pores can provide a habitat for soil microorganisms that facilitate nutrient cycling.

The ability of biochar amendments to reduce the bulk density of soils is an important mechanism by which biochar enhances the physical condition of soils. The bulk density of tightly packed biochar powder (<1 mm particle size) is about 0.5 g cm⁻³, but the bulk density of biochar varies substantially depending on the ash content, internal porosity, and particle size. The mixing of biochar with a mineral soil reduces the bulk density of the soil by a factor that is significantly greater than that would be predicted from the volumetric mixing of the low-density biochar with the higher density mineral soil. The cause of this synergistic effect is not entirely clear.

One of the more remarkable features of biochar is the apparent enhancement of microbial activity, especially mycorrhizal fungi,^[11] which increase soil organic matter turnover and nutrient cycling. The cause of this increase in soil microbial activity is not clear; however, several factors such as lower bulk densities, improved aeration, higher pH values due to the liming effect of biochar, sorption of bioavailable dissolved organic matter by biochar particles, and the porosity in biochar providing a favorable habitat for soil microorganisms all may contribute to the observed enhanced soil microbial activity. Enhanced soil microbial activity is indicated by increased CO₂ emissions resulting

from mineralization of biologic tissue and soil organic matter. Wardle, Nilsson, and Zackrisson^[12] suggested that biochar-induced increased mineralization of soil organic matter might have an adverse effect on the levels of soil organic matter. However, any analysis of the net effect of biochar on the levels of soil organic matter must include both the rate at which existing soil organic matter is mineralized and the rate at which new soil organic matter is being formed. Increased nutrient cycling associated with enhanced microbial activity increases nutrient availability to plants, which typically results in increased plant growth and increased input of new residue to soils. Furthermore, by adsorbing dissolved organic compounds (Fig. 1) during the decomposition of organic residues, biochar may increase the efficiency by which new residues are transformed into stabilized soil organic matter. Scientific studies that consider the effects of biochar on both inputs and losses of soil organic matter are lacking. However, the presence of high levels of both biochar and biogenic soil organic matter in the Terra Preta soils suggests that the net effect of biochar is to sustain high levels of biogenic soil organic matter.

Most studies report small to substantial yield increases following soil biochar applications,^[13,14] however, there are also a few reports of crop yield decreases. The cause of these yield decreases is not always clear. However, biochar quality appears to be very important. Biochars that contain substantial amounts of bioavailable C have the potential to immobilize N and induce N deficiencies. Biochar binds micronutrients such as copper very tightly, and it may be possible to induce micronutrient deficiencies in some soils by adding too much biochar. Most biochar is a liming agent, and when applied to calcareous soils or when too much biochar is applied to a neutral or acidic soil, biochar could increase the soil pH to the point that some micronutrients are rendered insoluble and thereby induce micronutrient deficiencies. Furthermore, biochars that are exposed to pyrolysis vapors during or after the production of the biochar may contain significant levels of phytotoxic phenolic compounds, and the release of such phenolic compounds from biochar could inhibit plant growth. On the contrary, most biochars strongly adsorb phenolic compounds, thereby reducing their bioavailability and leaching.^[15] For example, Garnett et al.^[16]

observed that biochar adsorbed phenolic compounds from leaf litter extracts and enhanced seedling growth relative to controls exposed to leaf litter extracts without the biochar. Therefore, anyone considering the use of biochar as a soil amendment should carefully consider the quality of the biochar before applying it to soil; some biochars will inhibit plant growth while others will enhance plant growth.

SUMMARY

Biochar has the capacity to retain bioavailable water and is a very strong adsorbent of plant nutrients and dissolved organic compounds. Biochar is an effective soil conditioner that reduces soil bulk density and increases the capacity of soils to retain and supply nutrients and water to grow plants. Because of these positive effects on soil quality, most studies have reported enhanced plant growth for soils amended with biochar; however, caution is urged as biochar quality is critical. Some biochars have the capacity to tie up nutrients whether by immobilization, by nutrient adsorption, or by raising the soil pH to the point that the nutrients are no longer bioavailable.

Biochar: Soil Carbon and Fertility

Adam O'Toole

Daniel Rasse

Climate and Environment Division, Norwegian Institute of Bioeconomy Research (NIBIO),
Aas, Norway

Abstract

Biochar is a multipurpose soil amendment for addressing two key global problems, namely soil degradation and climate change. The unique properties of biochar reside in the nature of its carbon (C) structure, which is more persistent in soils than that of uncharred organic matter. When made and applied correctly, biochar can remain in soil for hundreds of years. This characteristic gives biochar a comparative advantage over alternative methods of soil C sequestration in terms of both storage duration and its compatibility with conventional tillage operations. Parallel to C sequestration effects, biochar application appears to promote soil quality and crop productivity. Studies show that biochar influences the fertility of soils via a variety of mechanisms including soil pH increases in acidic soils, direct plant nutrient supply, and increases in soil water retention. Indirect effects on plant growth have also been found due to the unique surface properties of biochar, which promote a buildup of plant-available nutrients in soils. Biochar technology is largely at the research and pilot stage. Operational implementation will require robust and cost-efficient methods for product quality and C sequestration assessment, better understanding of effects on soil biota, and mechanisms for paying farmers for the ecosystem services of biochar.

INTRODUCTION

Biochar is the term given to define charcoal when it is used for sequestering soil carbon (C) and improving soil fertility. In a soil science context, the study of biochar overlaps with the previous research on pyrogenic C in soil derived from vegetation fire. The study of biochar has gained significant attention post-2000 with the pressing need to find mitigation options for climate change. Biochar is produced via the thermal process of pyrolysis, which heats biomass at temperatures $>350^{\circ}\text{C}$ in an oxygen (O_2)-depleted atmosphere. During pyrolysis, molecular structures within the feedstock undergo chemical transformation where light compounds are released in the form of gas and oils, leaving behind more complex compounds, such as lignin, which are transformed into polyaromatic C structures. These polyaromatic structures are difficult for microbes to consume as an energy source. Therefore, converting biomass to biochar generates a form of organic matter that can remain in soil for a long time. The persistence of biochar C in soil depends upon a variety of factors including climatic and soil conditions, mode of application, and how the biochar was made (production temperature, pyrolysis technology, and feedstock type).

In addition to its mitigation function for climate change, biochar has also shown to improve the fertility of soils. Research into the agronomic benefits of biochar has been partly inspired by the discovery of the fertile

black soils in the Amazon known as *Terra preta*. *Terra preta* are Anthrosols that are typified by a profile rich in soil organic C, pottery remnants, and biochar, the latter making up $>90\%$ of the soil organic C in investigated *Terra preta* soils.^[1] *Terra preta* is remarkable for its enduring fertility and ability to retain high levels of soil organic matter despite moist and warm tropical conditions, which normally lead to rapid soil C loss. Soil scientists have made a concerted effort within the 20th century to determine to what extent the “*Terra preta* effect” of enduring soil fertility and high C content is due to the addition of biochar.

Modern biochar trials have only been started within the 20th century, with many of them not older than a few growing seasons, and therefore, we can only report on short-term agronomic effects. Whether biochar increases soil fertility depends on whether it enhances the chemical, physical, and/or biological conditions that are necessary for optimal plant growth. Here, we summarize the main findings of biochar research and knowledge as regard to its use to mitigate climate change and to improve soil quality and crop yields around the world.

SOIL C SEQUESTRATION, C CYCLING EFFECTS, AND BIOCHAR C STABILITY

It has been known for a long time that vegetation fires can generate long-lived charcoal forms in soils;^[2] however,

the yield of charcoal formation in a vegetation fire is very low, estimated around 5%.^[3] The reason for the low charcoal yield generated by a vegetation fire is that most of the biomass is fully oxidized while the inside of larger stems often does not reach sufficient temperatures due to insufficient heating times. In contrast, modern pyrolysis technologies can control temperature, O₂ exposure, and heating time to produce higher and more stable yields of biochar C.

In theory, C sequestration with biochar technology presents multiple advantages as compared to traditional methods for organic matter management such as composting or plowing of crop residues.^[4] The main advantage is that the resulting biochar is much more persistent in soils than the original feedstock. Although a wide range of estimated residence time for biochar in soils has been reported depending on pyrolysis conditions, many studies show that the constitutive C of well-engineered biochar remains in soil well over the 100-year threshold, which is used as a convention for the permanent removal of carbon dioxide (CO₂). By contrast, most of the C in fresh biomass, such as straw, is lost to the atmosphere in the form of CO₂ within a few years after incorporation into soil. A small fraction of fresh biomass C becomes part of a more protected pool of soil organic C.^[5] However, even soil organic C itself has a mean residence time in soils of about only 50 years,^[6] i.e., well below that of biochar. Fig. 1 illustrates the large potential for increased C storage in soils through pyrolysis of plant residues and incorporation of the resulting biochar into soil. The soil organic C content of a cereal field with plowed-in residues reaches a simulated equilibrium of 30 tons C ha⁻¹ in its Ap horizon, under the assumption that 12% of shoot biomass is transformed into soil organic matter with a turnover rate of 2% per year. Exporting the shoot biomass off-farm rather than

plowing them in would result in a progressive decrease of nearly 50% of the organic C content of the soil. By contrast, if we assume that 50% of the shoot biomass is converted to biochar (with a conservative mineralization rate of 1% per year), we would nearly quadruple the amount of C sequestered into the Ap horizon, reaching about 120 tons C ha⁻¹ after 250 years (Fig. 1). This biochar effect on C sequestration would be even larger if we logically assume that the increased soil organic C content has a moderate positive effect on plant yield and biomass production. This simple simulation exercise illustrates that it is not necessary to assume millennial-scale stability for biochar products in soil in order to increase several fold the amount of organic C being sequestered in agricultural soils.

The C sequestration effect obtained with biochar addition is insensitive to changes in management practices because well-engineered biochars decompose slowly in soil. This is not the case for other C sequestration methods. For example, all C sequestration gains with a plantation forest can be lost very quickly in a fire or storm event. Soil C stocks can be increased with continuous amendments of compost and manure, no-till practices, and conversion of arable lands to pasture. However, once these C sequestration measures are discontinued, the soil organic matter stocks rapidly decrease due to the inherent degradability of non-pyrogenic organic matter in soil. By contrast, the enhanced stability of biochar C in soil gives a farmer the possibility to continue ploughing if they wish while still retaining soil C.

More streamlined accounting for soil C in soil C credit/offset programs is another potential advantage of biochar technology.^[4] In theory, all that is needed are records of applied biochar quantities and an estimate of its mineralization rate in soil. This gives biochar an advantage over other soil-based methods, which require expensive and regular monitoring campaigns in order to verify the changes in soil C content. However, little research has been conducted in documenting the physical transport and fate of biochar in soil. Due to the low density of biochar and its initial hydrophobicity when first made, it is likely that some of the biochar will be eroded or leached from the soil. Downstream environmental effects of this loss have not been well documented, and more research is needed here.

In spite of its many potential advantages, i.e., permanent removal, flexibility of land management, and ease of implementation in C accounting schemes, biochar remains mostly at the research and pilot stage. Encouraging biochar use in modern farming will require research to identify where biochar will lead to added value in terms of agronomy, energy, and/or economy. Carbon financing is likely needed from public and private funds to give farmers an incentive to convert their biomass to biochar and store more C in soil. But before this happens, a scientific consensus is needed on the best

Fig. 1 1. Simulated evolution of soil C stocks comparing straw restitution (12% transformed into soil organic C, which mineralizes at 2% per year) and straw pyrolysis into biochar before restitution (50% biochar yield and 1% mineralization per year).

method/methods to estimate the stability of biochar in soil. These methods need to be robust and cost-efficient. One method proposed by an international panel uses the molar hydrogen/organic C ratio of biochar as a proxy for biochar C stability.^[7]

BIOCHAR'S EFFECT ON REDUCING NON-CO₂ SOIL GREENHOUSE GAS EMISSIONS

In order to evaluate the total greenhouse gas mitigation potential of biochar, it is imperative to determine its effect on the other two major greenhouse gasses—methane (CH₄) and nitrous oxide (N₂O). N₂O has a global warming potential 298 times that of CO₂ on a 100-year time horizon, and, therefore, even limited changes in N₂O emissions induced by biochar application could significantly eat away at the C sequestration benefits. Fortunately, the vast majority of studies show that biochar reduces N₂O emissions, especially in poorly drained soils where denitrification takes place.^[8] In these soils, N₂O is a by-product of microbial processes and occurs mostly when nitrate is not fully denitrified to nitrogen gas.

The story regarding biochar's effect on CH₄ is uncertain, with studies showing both increases and decreases in CH₄ emissions due to biochar addition. Under some experiments, biochar has increased CH₄ uptake to soil by increasing aeration of the soil and making soil pH conditions more favorable for CH₄-consuming methanotrophs.^[9] In another study, biochar has increased CH₄ at higher moisture rates due to its ability to extend the periods of water saturation and anoxia, which encourages CH₄-producing methanogens.

THE ROLE OF BIOCHAR IN IMPROVING SOIL FERTILITY IN AGRICULTURAL SYSTEMS

Plant growth is dependent on a combination of chemical, physical, and biological conditions in the soil. The extent to which biochar modifies these three main soil parameters

Fig. 2 Scientific efforts are investigating the effects of biochar on soil physics, chemistry, and biology.

depends on the inherent biochar properties, as influenced by the type of feedstock and the pyrolysis conditions, application dose rates, and the degree to which it interacts with the inorganic, organic, and living matter in the soil (Fig. 2).

Here, we will outline some of the main findings from biochar related to its effects on plant yield and nutrition, soil physics, and soil biology.

PLANT YIELD AND NUTRITION

A meta-analysis of biochar research showed that on average biochar additions to soil increase yield; soil pH; soil C, nitrogen (N), and phosphorus (P); and concentrations of plant tissue potassium (K).^[10] Another meta-study in 2011 reported an average increase in crop yield of 10%, which was more pronounced in acidic and coarse-textured soils.^[11] In highly degraded soils, which receive little or no fertilizer, biochar incorporation directly contributes to plant nutrient supply notably through its ash content. The nutrient content of biochar depends on the feedstock it is made from. For example, biochar made from poultry litter is high in P, while straw- and grass-based biochars are often high in K. Nitrogen-rich feedstocks such as poultry litter and biosolids can be used for making biochar, but a significant proportion of the N content is volatilized during pyrolysis, and the remaining N is not easily mineralizable.^[12] This should be taken into consideration when evaluating the total environmental footprint of a biochar pyrolysis system. More important than the nutrient content of the biochar is its ability to capture nutrients when mixed with other nutrient-rich sources. Studies have shown beneficial synergies by incorporating biochars into compost, biogas, and manure management systems. Here, it is possible to take advantage of the large pore space (Fig. 3) of the biochar to store nutrients and water and reduce the loss of N to groundwater and the atmosphere.

Fig. 3 Cross section of the stem of wheat straw biochar. **Source:** NIBIO.

SOIL PHYSICAL EFFECTS

Biochar can also modify soil physical properties, such as soil water retention and bulk density. Biochar has a low bulk density ranging from 0.2 to 1.0 g cm³, depending on the feedstock it was made from.^[13] Thus, additions of biochar to mineral soil (which usually has a bulk density of 1.3 g/cm³) can reduce the overall density of the soil. Biochar is a highly porous material somewhat like a sponge and can adsorb many times its own weight in water. This property can be of benefit for increasing soil water retention in sandy soils, especially during drought conditions.^[14,15] In heavy clay soils, biochar additions have shown to increase the stability of macroaggregates and aid in reducing the mechanical strength and penetration resistance of hardsetting soils, which is beneficial for root growth.^[16] In horticulture, biochar has been successfully used in high concentrations (50% to 75%) as a replacement for peat, which is considered a non-renewable resource.^[17] Biochar is similar to peat in that it can hold a lot of water, but has an advantage over peat in that it does not shrink when it dries out.

SOIL BIOTA

While biochar, due to its higher aromatic C content, is unlikely to be a significant source of energy for microbes, there have been a number of reports that biochar can indirectly affect microbial communities. This could be for a number of reasons, including the following:

1. Biochar is usually alkaline and raises soil pH, which can have significant effects on microbial processes;
2. The porous structure of the biochar provides a refuge for microbes, which may alter predation levels and thus trophic turnover; and
3. The presence of volatile C compounds on the surface of biochar, which may have either inhibiting or stimulating effect on microbial communities.

Generalizing biochar effects on soil biota is difficult due to the heterogeneity of biochars and their chemical and physical properties. Short-term effects might not last in the long term. For example, biochar application can induced short-term increases in gross N mineralization, nitrification, and immobilization rates; however, this effect appears to fade with time.^[18] Faunal activity is also affected by biochar, both through direct pH and chemical effects and through indirect changes in bacteria populations, which are a food source for the soil fauna. A meta-analysis on the effect of biochar on earthworm populations showed a short-term negative effect but no long-term impact.^[19] Further studies investigating soils with historically large biochar contents may shed more light on the long-term effects of biochar on microbial

populations and their ecosystem functioning. For example, one study compared *Terra preta* Anthrosols rich in biochar with adjacent soils sharing the same mineralogy and texture and found large differences in bacterial community composition.^[20]

CONCLUSION

Biochar is the subject of intense research within the soil science community as a multipurpose material for both storing more C and improving the fertility of soils. Biochar has been tested in most of the world's major agricultural countries and climatic zones, and much has been learned about how it affects soil chemistry, physics, and biology. The applicability of biochar as a robust method for storing more C in soils seems well proven, but large-scale implementation will require more research and development on intrinsic biochar properties and resulting effects on agroecosystems.

ACKNOWLEDGMENT

The authors would like to acknowledge the financial support of the Norwegian Ministries of Agriculture and Environment that makes funding available for them to disseminate scientific knowledge to a wider audience on agricultural and climate change-related topics.

Biodegradation and Bioremediation

Owen P. Ward

Ajay Singh

Department of Biology, University of Waterloo, Waterloo, Ontario, Canada

Abstract

Biodegradation processes mediate recycling of organic materials in the environment. In bioremediation processes, microorganisms and plants participate in the biodegradation and removal of hazardous contaminants to restore the polluted environment. Although microorganisms thrive in aqueous environments, the majority of organic chemicals and environmental contaminants are hydrophobic and sorb to soil particles. To access these contaminants, microbes may interact directly with the contaminant or soil particulates or both or secrete biosurfactants to mobilize the contaminant into the aqueous phase. A variety of *in situ* and *ex situ* bioremediation strategies are employed, aimed at promoting the biodegradation of chemical pollutants present in the contaminated medium.

INTRODUCTION

In their most general sense, biodegradation processes are central to all biological systems. In these processes, cells transform and recycle biological and synthetic chemicals and materials into smaller molecules to generate energy and/or metabolic intermediates needed for cell functioning including maintenance, biosynthesis, and growth. Indeed, these processes also contribute to the unique adaptation properties of organisms, e.g., enabling microbes to adjust to changing environments by making the requisite biochemical and physiological changes mediated by biodegradative and biosynthetic metabolic processes. Bioremediation represents an important applied segment among these biodegradation processes in which technologies are generally engineered and optimized to exploit the same biodegradation capabilities especially of microbes, for the removal of organic contaminants and, sometimes, metal contaminants from the environment. The principal objective of this entry is to provide an overview of bioremediation processes and systems as well as a perspective on developments and future prospects. General principles of biodegradation processes are first considered to provide a context for addressing bioremediation technologies.

BIODEGRADATION OVERVIEW

On a macro scale, biodegradation processes often mediate recycling of organic materials, including animal, plant, and microbial materials, present in the environment. Enzymes secreted by microbes and other species attack and depolymerize the principal biological polymeric structures, namely complexes containing carbohydrates, proteins, nucleic acids, lipids, and their derivatives into oligomeric

or monomeric components, which may be taken up and metabolized by cells. These processes are promoted in the digestive systems of humans, animals, and other species mediated by endogenous enzymes from these organisms or supported by the microbial populations present or both. These processes also occur everywhere in the environment where microbes can thrive, most notably in soil and in aqueous media. Processes in soil are enhanced around plant roots where nutrients released from the roots support the growth of plant through growth-promoting bacteria. Such processes are also actively promoted in the practices of agriculture and horticulture and in myriad solid and liquid waste treatment systems. Some examples of general environmental processes and practices for the biodegradation of natural organic materials include processes for silage making, composting, and wastewater treatment (Table 1). The reader is referred to references^[1–3] for further discussion of these topics.

BIOREMEDIATION OVERVIEW

Industrial-scale processes for the recovery of petroleum and the manufacturing, distribution, and use of chemicals invariably lead to the transfer of chemical contaminants into the environment, most notably into soils, groundwater, shorelines, and water bodies. These contaminants range from alkanes and mono- and polycyclic aromatic hydrocarbon (PAH) compounds, naturally present in crude oil or generated through combustion, to high-volume synthetic chemicals including chlorine-, nitrogen-, and phosphate-containing organic chemicals and many others. In addition, soils become contaminated with inorganic chemicals. Just as microbes have the ability to concentrate and accumulate metals in wastewater treatment processes, so too specific

Table 1 Example processes for the biodegradation of natural organic materials.

- *Silage-making processes*, where fibrous plant materials are rendered more digestible for animal feeding by the conversion of sugars to organic acids and some enzymatic cellulose/hemicellulose degradation, mediated by microbial anaerobic digestion.
- *Composting processes*, used to aerobically transform plant and other biological and organic materials, most frequently derived from agricultural, horticultural, food, and municipal wastes. A variety of microbial species, most notably fungi and bacteria including mesophiles and thermophiles, participate in these exothermic biodegradative processes to generate beneficial organic fertilizers devoid of pathogens, which are killed as thermophilic conditions are achieved.
- *Biological wastewater treatment processes*, where the objective is to remove contaminants from domestic, municipal, or industrial waste streams. Microorganisms are primarily responsible for aerobic and anaerobic degradation and assimilation of the organic components together with some removal/concentration of heavy metals. The resulting accumulated biosolids may be further processed and transformed into beneficial organic fertilizers for use in agriculture.

microbes can accumulate or transform some of these inorganic species or both.

The extent of the threat to the environment posed by petroleum and organic chemicals may be appreciated by reference to the production volumes of these products. Global crude oil production and world refining capacity are approaching 80 million bbl per day. Estimates for global production volumes of synthetic polymers and plastics approximate to 140 million tons per annum.^[4] In the United States alone, the annual production volumes of each of ethylene, propylene, vinyl chloride (VC), and benzene range from 5 to 20 million tons, with volumes of many other organic chemicals ranging from 1 to 5 million tons.^[5]

Some of the most widely distributed organic environmental contaminants are aliphatic and aromatic hydrocarbons, including alkanes, mono- and polycyclic aromatics, present in crude oils or in refined oil fuels or petrochemicals; halogenated aliphatic, especially chlorinated species including chlorinated methanes, ethanes, and ethenes such as trichloroethylene, dichloroethene, perchloroethene, and VC; mono- and polyhalogenated phenols and benzoates, including pentachlorophenol; polychlorinated biphenyls (PCBs); chloroaromatics including 2,4-dichlorophenoxyacetate, dichlorodiphenyltrichloroethane, and related compounds; nitroaromatics including nitrobenzene and 2,4,6-trinitrotoluene (TNT); organophosphates; nitrate esters (including glycerol trinitrate); nitrogen heterocycles (including the explosive compound hexahydro-1,3,5-trinitrotriazine or RDX); and polyesters, polylactates, polyurethanes, and nylon.^[6,7]

The recognition that microbes in soil could degrade, transform, or accumulate many of the chemicals polluting the soil provided momentum for the undertaking of research to exploit these activities to clean up contaminated soil and other media, using processes termed as bioremediation. Indeed, the observed effectiveness of bioremediation as a process for the degradation of oils contaminating the shorelines at Prince William Sound, Alaska, due to the *Exxon Valdez* oil spill led to the development of a variety of strategies for the application of bioremediation processes for soil remediation.^[8,9] Bioremediation is generally considered to be the low-cost option in comparison to physical and chemical alternatives.^[10]

Bioremediation technologies may be adapted to a variety of different contaminants and environmental conditions, and in particular, conditions can be developed for the selection and enrichment of microbial populations having the requisite and unique degradation abilities to remediate the specific contaminants present at a particular site.^[11] Bioremediation technologies are also advantageous where contaminants have become diluted or widely dispersed over time.

A vast array of physical environments exist where biodegradation and bioremediation processes may thrive. Broadly speaking, these environments will all contain water or at least be moist because the presence of water is a prerequisite for microbial growth and biodegradation activity. The nature of the microbial type or population that develops will be influenced by a wide range of factors including the physical properties of the medium; salt concentration; solid content, surface properties, and particle size; nature and concentration(s) of contaminant(s); nature and concentration of nutrients present to support microbial growth; relative humidity; presence of oxygen or other electron acceptors; pH; and temperature.

CONTAMINANT BIODEGRADABILITY

Although many organic chemicals are biodegradable by microbes present in the environment, other natural or synthetic chemical structures exhibit resistance or recalcitrance to biodegradation and tend to persist in the environment for prolonged periods of time. The microbial transformation of organic pollutants is mediated primarily by enzyme-catalyzed reactions but often with the support of other cell components, associated with cell surfaces, surfactants, chelators, vesicles, and organelles. The biotransforming enzymes may be located within the cell protoplasm or be membrane associated (or a combination of these) or indeed in a few cases may be extracellular. A good example of a combined intracellular/membrane-bound system is the *alk* gene system for alkane degradation, whereas extracellular fungal peroxidases and laccase are non-specific mechanisms for the attack of organic pollutants, mediated by the generation of free radicals.^[11] The microbial enzyme

transformation of contaminants may lead to complete contaminant mineralization or to the production of breakdown products that may be assimilated into the cells' central pathways for energy or biomass production or both. Alternatively, contaminants may be partially degraded or transformed into metabolites, which the cell cannot further utilize, whereby such metabolites may accumulate in the cell or be excreted. These metabolites may be further transformed by other cell types, among the multitude of microbes present in the ecosystem, which may have different metabolic capacities. Alternatively, the metabolites may be generally recalcitrant to biodegradation and may bioaccumulate. Contaminants in well-aerated environments will predominantly be degraded by aerobic metabolic processes, whereas contaminants in a non-aerated subsurface environment may be anaerobically degraded.

A review of aerobic pathways for the biodegradation of organic contaminants including petroleum hydrocarbons, chlorinated hydrocarbons, nitroaromatics and nitrogen heterocycles, organophosphate derivatives, and plastics reveals the following reaction types: dioxygenases, monooxygenases, hydroxylases, ligninases, and reductases among others. Anaerobic biodegradations typically involve initial activation mechanisms such as carboxylation, methylation, hydroxylation, and dehydrogenation followed by additional reactions, anaerobic reductions, and hydrolytic reactions.^[12]

Microbes have the potential to remediate metals in contaminated media by exploiting a combination of mechanisms including precipitation, sorption, biosurfactant complexation, biofilm entrapment, and metabolic uptake. Some microbes can also transform metals including radionuclides, e.g., by reducing mercury into a volatile form, which can be removed. In metal bioremediation applications, there is particular interest in exploiting microbes, which have been isolated from mine tailings and heavy metal-contaminated sites, as these strains exhibit superior metal-scavenging capacities, greater resistance to metal toxicity (sometimes mediated by metal efflux mechanisms), and ionizing radiation.^[13] Examples of interesting strains for these applications include certain *Pseudomonas* species, including recombinant strains, *Ralstonia eutropha*, *Thiobacillus ferrooxidans*, and *Deinococcus radiodurans*.

CONTAMINANT TOXICITY

The principal concern regarding chemical contamination of the environment relates to contaminant toxicity. Many of the chemical contaminants, but especially the more recalcitrant chemicals, are toxic to higher life forms or are known as carcinogens or both. As such, their presence represents a threat to human and animal health. Many of these chemicals are classified as hazardous by national regulatory agencies, including the U.S. Environmental

Protection Agency (USEPA). For example, 16 PAHs are considered to be priority pollutants by the USEPA and 7 of these are classified as probable human carcinogens.^[14]

As a result of chemical contamination of the environment, toxicity concerns do not just relate to the toxicities of the original chemical compounds transferred. There are many examples where the "parent" contaminant may get chemically or biologically transformed into reaction products or catabolites, which are as toxic as or even much more toxic than the parent compound. For example, surfactants present in detergents, such as nonylphenol ethoxylates, are often biotransformed into nonylphenol end products with endocrine-disrupting activity as a result of microbial transformation.^[15] The presence of strong chemical oxidizing or reducing agents in the contaminated medium can give rise to non-specific conversions of the contaminants into more reactive and more toxic products.^[16]

In heavily contaminated media, the toxicity of the medium may hinder the implementation of bioremediation strategies as a result of the contaminant, at a higher concentration, being toxic to the microbial population that may have the metabolic capability to biotransform the contaminant. In a manner akin to antibiotic resistance, some microbial cells have developed resistance to specific toxic organic compounds such as toluene, by using efflux pumps to extrude toxic contaminants from the cell cytoplasm or periplasmic space.^[17] It is also thought that, where toxic contaminants are only partially transformed by one species, efflux pumps may have the potential to excrete the metabolites such that they may be made available to other members of a consortium with the capacity for the degradation of excreted metabolites. In metal bioremediation applications, there is particular interest in exploiting microbes, which have been isolated from mine tailings and heavy metal-contaminated sites, as these strains exhibit greater resistance to metal toxicity (sometimes mediated by metal efflux mechanisms) and ionizing radiation.^[13]

The extent of toxicity of a known toxic contaminant cannot be simply related to its concentration in the contaminated medium. Actual toxicity may be diminished by the sorption of contaminant to soil particles or organic matter. In addition, biological species present in or added to the contaminated medium may adsorb the contaminant or secrete biological molecules including chelators or surfactants, which effectively sequester the contaminant, thereby reducing its toxicity. Arguably, the presence of other components in the contaminated medium or indeed produced by the biological organisms present could enhance toxicity. For example, a hydrophobic contaminant, with a tendency to sorb to soil, might become mobilized and solubilized by the presence of lipids or surfactants and possibly become more toxic to the organisms present.

Scientists have developed toxicity-testing methods, whereby contaminant-sensitive organisms, including

microbes, algae, plants, fish, macroinvertebrates, and cultured cell lines, are used as biomonitors of pollutant accumulation in soil and aquatic systems and also for following the reduction in the toxicity of the contaminated media as a result of the implemented remediation processes. These biomonitoring tests rely on observing whole-organism biological impacts, related, e.g., to growth, behavior, reproduction, or mortality. Alternatively, toxicity tests may involve the measurement of intracellular biomarkers, e.g., heat shock proteins; enzymes including antioxidant enzymes, DNA repair enzymes, acetylcholinesterase, cytochrome P450 monooxygenase, and glutathione S-transferase; and DNA mutations or chromosomal defects.^[18]

CONTAMINANT BIOAVAILABILITY

Microbes generally thrive and grow in aqueous phases and are most efficient at accessing nutrients that are water soluble. However, petroleum components, as well as most other chemical contaminants, are water insoluble or hydrophobic and hence less bioavailable to microbes. In addition, soil is the most dominant medium for these contaminants, and hydrophobic contaminants tend to bind strongly to soil particles, thereby further reducing their bioavailability to microbes capable of biodegrading the contaminants and rendering them more persistent in the environment. Soil bioremediation processes require adequate amounts of water present in the soil to support microbial activity, and the contaminant-biodegrading organisms have the means to access the hydrophobic or soil particle-bound contaminants or both. Two general natural microbial mechanisms are known to facilitate this contaminant access. First, cells may sorb and uptake the contaminant by direct interaction between the microbes and the hydrophobic substance/particulate matter. Alternatively, the microbes may secrete biosurfactants into the surrounding environment, which may pseudosolubilize and mobilize the contaminant through micelle formation, which facilitates contaminant contact with the microbes and promotes cellular uptake of the hydrophobic substrate. As amphipathic molecules, biosurfactants contain both hydrophilic and hydrophobic ends. In the presence of hydrophobic contaminants in an aqueous environment, micelle formation results when the biosurfactant molecules associate with and solubilize the hydrophobic contaminant in the center of the micelle, while the hydrophilic ends of the biosurfactant molecules remain on the outside of the micelle in contact with the aqueous phase.^[19,20] These contrasting processes were well illustrated by culturing oil-degrading strains of *Pseudomonas* sp. and *Rhodococcus* sp. separately and together in aqueous media supplemented with crude oil. The *Pseudomonas* was located predominantly in the aqueous phase and did not associate with oil droplets, whereas the *Rhodococcus* cells were concentrated at the

oil–water interface.^[21] The greatest degradation occurred where both mechanisms were in play, when a coculture of the strains was used.

In bioremediation processes, the natural mechanisms of contaminant mobilization and pseudosolubilization, promoted by biosurfactants, may be replaced or supplemented by the use of added chemical surfactants. The chemical, namely nonylphenol ethoxylate surfactant, substantially increased crude oil biodegradation by a consortium of oil-degrading organisms.^[22] However, biosurfactants or chemical surfactants may also inhibit the degradation of contaminants, whereby isolating the contaminant in the center of the micelles effectively may prevent uptake by the degrading microbes. For example, Billingsley et al.^[23] observed that at chemical surfactant concentrations above the critical micelle value, the presence of an anionic surfactant promoted, whereas non-ionic surfactants inhibited, biotransformation as compared to no surfactant controls. These and related topics are discussed in more detail by Ward.^[24]

GENERAL MICROBIAL APPROACHES TO THE REMEDIATION OF CONTAMINANTS

Two general strategies for the implementation of bioremediation processes were identified around the time of the *Exxon Valdez* oil spill and cleanup, biostimulation, and bioaugmentation. The objective of biostimulation processes is to promote the growth of the segment of microbes present in the contaminated environment, which can degrade the contaminants. If the contaminated environmental medium does not contain microbes, which can degrade the contaminant, bioaugmentation with a selected inoculum already acclimated to grow on the contaminant may be needed.

Biostimulation

Most organic contaminants in the environment are carbon rich, and the growth of organisms that can use this carbon source is usually limited by the availability of other nutrients, supplements, and electron acceptors. Nutrients that are most widely used in aerobic bioremediation processes are nitrogen and phosphate, and getting oxygen to the medium is often the most challenging engineering component. In surface soil bioremediation processes, oxygen is supplied from the atmosphere, and atmospheric oxygen is also exploited in reactor-based processes, engineered soil piles, and *in situ* processes by sparging air to the contaminated soil or slurry.^[25] Other strategies involve the supply of pure oxygen gas, ozone, or manganese peroxide. In anaerobic bioremediation, the delivery of adequate amounts of suitable electron acceptors to the medium is a priority strategy. Examples of electron acceptors are sulfate, nitrate, and ferric iron.

There are also other more specialized biostimulation approaches. Hydrophobic contaminants are less accessible to microbes, surfactants, biosurfactants, or indeed, easily biodegraded solvents and vegetable oils, agents may be added to solubilize these contaminants, releasing them from particulate matter and rendering them more amenable to biodegradation.^[19,20,26] Where contaminants are typically degraded by cometabolic processes requiring the presence of primary substrates, the remediation of contaminant may be stimulated by the addition of a primary substrate. A further example of biostimulation, in case of the aerobic bioremediation of clays having low porosities that resist aeration/oxygen delivery systems, is to add low-density bulking agents such as plant materials, sawdust, and wood chips to increase the porosity of the medium and allow easy delivery of air.

Bioaugmentation

Examples where a bioaugmentation strategy has been beneficial include the bioremediation of very recalcitrant contaminants such as TNT, phthalate esters, and carbon tetrachloride.^[27,28] This strategy is also necessary where the contaminants are not degraded by natural organisms but where recombinant organisms have been engineered, which are capable of degrading the contaminant. Bioaugmentation is also applicable where highly accelerated biodegradation processes are required, e.g., for accelerated reactor-based processes for the remediation of hydrocarbon sludges.^[29] In many cases, bioaugmentation has been shown not to enhance biodegradation rates beyond what may be achieved through biostimulation, as was most notably illustrated in case of the studies during the *Exxon Valdez* oil spill cleanup.

BIOREMEDIATION TECHNOLOGIES

There are a wide range of possible approaches to the bioremediation of contaminated environments. They include soil bioremediation processes involving natural attenuation, *in situ* subsurface treatments and use of biopiles and composting approaches, and landfarming and bioreactor treatments. Crude oil spills at sea may be addressed through shorelines or deep-sea bioremediation strategies.

Monitored Natural Attenuation or Intrinsic Remediation

This process is the simplest and least-invasive bioremediation approach.^[30] The process presumes that the environment contains sufficient nutrients to support the indigenous microbial population in the biodegradation of contaminants. Oxygen availability is often a rate-limiting factor although anaerobic biodegradation may also be important.

Intrinsic remediation processes may proceed for years, if not decades, as was shown with the remediation of PCBs in the Hudson riverbed.

In situ Subsurface Bioremediation

This approach involves designing a subsurface configuration to allow growth and contaminant biodegradation by the microbes present through the efficient supply of nutrients, oxygen, or other electron acceptors through injector wells and air-sparging systems into the unsaturated or saturated zone, generally below the contaminated plume.^[31] Processes may include a soil vapor extraction or other vapor containment system to prevent the release of volatile contaminants from the site to the atmosphere.

Engineered Biopiles

Engineered soil biopiles are typically fitted with a series of aeration pipes to distribute air to the contaminated soil via positive or negative pressure.^[31] With soils contaminated with volatile hydrocarbons, the air pumps generally draw a vacuum such that air enters at the surface of the pile drawing any undegraded volatiles into the pipework system where they may be directed to a biofilter or other volatile organic carbon (VOC) treatment or collection system. The addition of bulking agents to the soil may be required to facilitate airflow through the soil, and care must be taken to control soil humidity such that growth and biodegradation processes are facilitated.

Soil Composting

In the application of composting strategies to soil bioremediation, biomaterials including wood chips or other plant materials are mixed with the contaminated soil in approximately equal amounts. As in general composting, aerobic biodegradation processes result in heat generation. Contaminants are degraded by the bacteria and fungi associated with the compost, and it is known that contaminants may also react irreversibly with plant and humic substance components.^[31]

Landfarming

This bioremediation approach involves surface atmospheric aeration processes enhanced by frequent tilling and maintenance of moisture levels at 40–60% saturation via sprinklers or other means. The process is applicable to *in situ* soils contaminated near the surface or to spreading and treating excavated soils at a designated landfarming location.^[31] Weathering, sorption, evaporation or volatilization, leaching, and photo-oxidation processes may cause the removal of certain hydrocarbon compounds during bioremediation, resulting in the overestimation of the extent of biodegradation.^[7]

Soil Bioreactors

Soil slurry bioreactors have advantages for bioremediation processes similar to the general fermentation and other bioprocesses, where those conditions in the mixture can approach homogeneity, and processes can be optimally controlled to promote microbial growth and contaminant biodegradation.^[26] Although capital and energy costs are high in these processes, high rates and extents of degradation may be achieved with high levels of process dependability and reliability.^[29]

Bioremediation of Shorelines

Marine shoreline bioremediation processes are challenging due to the potential for changing tides to wash away nutrients and microbes from the contaminated shore. The capacities of microbes to remediate contaminated soil, coastlines, and water bodies were first demonstrated on a large scale in the cleanup of the crude oil, which spilled from the *Exxon Valdez* tanker that ran aground off the coast of Alaska, near Prince William Sound. The remediation of hydrocarbons was promoted by the addition of specific oleophilic nitrogen fertilizers, which bound to the oil contaminants to support microbial growth and biodegradation.^[8,9] In contrast, the addition of microbial inoculants was ineffective.

Deep-Sea Bioremediation

The capacity of microbes to degrade crude oil at sea was illustrated during one of the world's largest environmental disasters, when the explosion at British Petroleum's Deepwater Horizon oil rig resulted in an estimated 4.9 million bbl of crude oil spilling into the Gulf of Mexico. On August 4, 2010, just 3 weeks after the well was capped, the U.S. government estimated that 50% of the oil was already gone from the Gulf, and the rest was being rapidly degraded. Dr. Kenneth Lee puts all of this in a scientific perspective as follows: "The consensus now is that microbial degradation was a major process responsible for cleaning up the Deepwater Horizon spill" (<http://www.dfo-mpo.gc.ca/science/publications/article/2012/01-25-12-eng.html>).

PHYTOREMEDIATION

In phytoremediation processes, the removal of inorganic or organic contaminants from media such as soil is promoted by plants or associations between plant roots and microbes in soil and aqueous media.^[32,33] In these processes, specific contaminants may be extracted, degraded, or immobilized. The mechanisms involved include the following: phytodegradation, where root exudates from the plant enhance microbial growth and contaminant biodegradation in the root surroundings; rhizofiltration,

where soluble contaminants are sorbed onto or into the roots; and phytoextraction involving uptake of metals by roots and their translocation in the plants. The plants may be harvested for disposal, and phytovolatilization, where contaminants taken up by the plant, are possibly, but not always, modified and transpired into the atmosphere.

AIR BIOFILTRATION

Contaminants in an air stream—e.g., VOCs—may be remediated through air biofiltration, whereby the contaminated air passes through a porous medium, which supports the growth of microbes as attached biofilms.^[34] The contaminants and oxygen are transferred from the air stream to the biofilm where biodegradation occurs, thereby decontaminating the air stream. Biofilter media include wood branches, bark or chips, peat, compost, synthetic media, coated ceramic or other particulates, and various combinations of these constituents. For effective performance, the biofilter environment must support efficient bacterial growth and facilitate effective transfer and sorption of contaminants from the air stream into the biofilm and access to the biodegrading microbes. The air stream or filtration medium must be appropriately humidified to insure that adequate water activity is maintained to support microbial growth and biodegradation while not oversaturating the medium such that air flow rate is retarded. The flow rate of the mobile phase (air in this case) is controlled to achieve a retention time in the biofilter sufficient to remove and biodegrade the contaminants in the air stream to a desired specification.

CONCLUSION

The purpose of surface or groundwater remediation is not only to enhance the biodegradation, transformation, or detoxification of pollutants but also to protect the quality of soil to maintain environmental quality and sustain biological productivity within the ecosystem boundaries. Although biological processes are typically implemented at a relatively low cost, the implementation of bioremediation technologies requires knowledge of interdisciplinary sciences involving microbiology, chemistry, engineering, ecology, and hydrogeology. Bioremediation methods have been successfully used to treat polluted soils, oily sludges, and groundwater contaminated by industrial chemicals and solvents, petroleum hydrocarbons, pesticides, and heavy metals.

Biodiversity and Sustainability

Odo Primavesi

Brazilian Corporation of Agricultural Research (EMBRAPA), Sao Paulo, Brazil

Abstract

The discussion on sustainability and biodiversity is focused at the level of the economic, agricultural, and policy sectors. However, there are different interpretations about this discussion, depending on the point of view of the party presenting the argument. In this entry, a global view is given to better understand the specificity based on the ecological principles that run nature. These principles remain as the source of inspiration and reference for the development of useful concepts to promote life and its quality.

BIODIVERSITY

What Is Biodiversity?

The U.N. Convention on Biological Diversity defines biological diversity as “the variability among living organisms from all sources, including terrestrial, marine, and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, between species, and of ecosystems.”^[1] Table 1 shows the global measured and estimated biodiversity in the world ecosystem.

Diversity is considered at different levels, between individuals, subspecies, species (most useful level), biological communities, and ecosystems. Species richness increases from colder to warmer latitudes. This is also true for the deep-sea species diversity.^[2]

The biological diversity is organized in a food web, with plants as base and humans as top of the pyramid and where the individuals act as producers or consumers or as recyclers or decomposers.^[3]

The soil is one of the most diverse habitats on earth and contains one of the most diverse assemblages of living organisms, mainly in the humid tropics; e.g., a single gram of soil may contain millions of individuals and several thousand species of bacteria.^[4] Table 2 shows a 100 × 30-cm-deep soil life in a pasture under temperate climate, remembering that in tropical conditions, there is a greater presence of termites, ants, larvae of beetles, and flies (Table 3). But in a broader view, it is advisable to consider soil as the undissociable soil–plant interaction. This will improve the degree of soil biodiversity, including the rooting system architectures or the so-called weeds, which are visible indicators of the degree of soil health.^[5]

In both natural and agricultural ecosystems, the different groups of soil biota interacting with plants (Table 4)

and their debris (Table 5) are responsible for, or strongly influence, the soil properties and optimize processes, including soil genesis; soil structure; carbon, nutrient, and water cycles; agrochemical movement or breakdown; and plant protection and growth^[3,6] They act in the processes of synthesis or production, transformation and decomposition, and consumption of organic material, affecting abiotic and biotic components, transportation, and soil engineering.

Therefore, soil biodiversity is a ground stone for sustainable agriculture, and it could be used as a good indicator of agroecosystem or soil health. Soil biodiversity does not necessarily refer to the number of individuals or species, but to the ratio of functional groups (Table 6) and the result or the tool of their activities, such as the presence and intensity of enzymatic activity.^[5]

What Is Its Importance?

In general, the arguments for biodiversity conservation and their importance are optimized environmental services (water cleaning up, recycling, biodegradation, soil permeabilizing, fertilization, etc.), food supplies, natural products, materials, medicines, fertilizers, pesticides, biological control agents, warning signs, genes, model systems for science, interesting wildlife, future options.^[2] Considering the process nature uses to develop a site or to recover its resting soil, it could be seen that biodiversity is the key tool used because it allows the complementary activity of individuals with different structures, needs, wastes, and functions to flourish in one of the diverse habitats created by the diverse interaction of the abiotic and emergent biotic factors occurring in this site. Nature uses biodiversity to produce the maximum of life and biomass per square meter and the available energy unity per year. But biodiversity is also the result of this settlement process of nature. At the same time, nature, by

Table 1 Global diversity of species.

Groups	Cataloged	Estimated	Note
Total	1.4 million	5–50 million	
Mammals	4,000	90–95%	
Reptiles and amphibians	10,848	90–95%	
Birds	9,040	94–100%	2–3 times in the tropics
Fish	19,056	83–100%	
Plants	322,311	67–100%	
	Trees	(50,000)	estimated for the tropics
Invertebrates	1,020,561	3–27%	
	Beetles		40% of arthropods
	Hemipterans	78,656	37.5% 10% of all insects
Microorganisms	5,760	3–27%	

Source: From Canada Agriculture and Agri-Food/Environment Bureau.^[1]

developing a short food chain into a complex food net, allows for a greater food availability and diversity for the individuals on the top of the food web or food pyramid, such as the humans, and also ensures their sustainability. When the biodiversity of the food web is disrupted by the establishment of a monoculture and when the environment is submitted to a degradation process, with malnourished plants and greater meso- and microclimate variability, the population outbreak of the more resistant members of the food web may occur as the so-called parasites and pathogens.^[5]

The reason for the species richness of the tropics is not known. Some ideas proposed take longer time to develop a new species and require greater supply of solar energy allowing more biomass production or more organisms per unit area.^[2]

Furthermore, the shallower soils in temperate climates show a greater chemical fertility, water-holding capacity, and clay activity, and the cold switch-off of biological activity will control it. In tropical conditions, the deep soils with low fertility, low water-holding capacity, low clay

activity, and the higher temperatures throughout the year will result in a greater number of interactions of water/drought × water table depth × nutrient × temperature × strong rains × wind × fire × photoperiod × oxygen (because of faster respiration rates); therefore, habitat variability occurs, with specificities settled in by the different plant species, the first component of the food web. The diversity of litter, defense substances, and root exudates produced by these different plant species and correlated fauna need to be recycled by a greater number of invertebrates and microorganisms in soil, because of their specificity in producing from 1 (bacteria) to 4 (fungi, insects) degradation enzymes. The high recycling activity in soil need to be considered because of the great importance of organic material (50–90%) as nutrient source for higher plants, besides the microbial activity of rock solubilizers, nitrogen (N)-fixing bacteria, or root surface expanding fungi (Mycorrhizae): biological fertility. In the tropics, with the great variability of habitats, the biodiversity of species and genes is the keystone for high biomass yield per high variable unit area, making the food net of an ecosystem very complex.

Biodiversity reaches the maximum level when the environment offers enough water and energy and low-to-medium level of nutrients, such as N and phosphorus, avoiding the very hard inter- and intraspecific competition from some more responsive or demanding species, occurring in high-fertility and very high-fertility soils, or the growth-restrictive conditions in very low-fertility soils, such as soils with high aluminum content.

SUSTAINABILITY

What Is Sustainability?

In 1987, the World Commission on Environment and Development established a definition of sustainability, known as the Brundtland Report. It stated that sustainable development meets the needs of the present without compromising the ability of future generations to meet their own needs. Although this definition has become widely publicized, the term sustainability is not limited to one precise definition.^[11]

Several authors have discussed the real meaning of sustainability and sustainable development.^[9,12] Munoz^[13] has presented a theoretical model of true sustainability or sustainable development ideas with global to local implications based on the need to balance social, economic, and environmental goals; stakeholders's interests; issues to induce or determine fairer or more appropriate development solutions, options, and actions. However, the social component can be seen as part of the environmental component, and the interaction of both will generate the economic component. So the environmental component is the keystone, and only its improvement and quality will allow us to reach a stable social welfare and sustainable economic profit.

What Is Nature Teaching Us?

Nature teaches us that the development of a natural primary environment (rocky) or degraded (soil in rest for some years to restore its productive potential) area, to an on-soil-based natural climax environment (mainly forest), with a high production potential, occurs with the development or restoration of a permeable soil, protected by a diversified vegetation with an active rooting system, and the return to soil of diversified organic material, the energy source for the diversified and active soil life. The soil vegetation and associated biodiversity interaction could improve the available resident water of a site and a longer water cycle. The more the resident water, the more the vegetation and the more permeable the soil. With more available resident water-permeable soil-diversified vegetation and soil life, there is an increase of relative air humidity and a decrease of the maximum temperature and the thermal amplitude, characteristic for desert environments. This friendlier mesoclimate helps more sensible plant and animal species to establish, and it improves biodiversity, with their additive and emergent characteristics.

Ecology considers desert ecosystems sometimes as sustainable as tropical forest ecosystems. So what level of environmental sustainability is desirable? The biological carrying capacity (BCC) is considered as the representative of this level. It represents the concept of primary productivity of an ecosystem, or the rate in which energy

Table 5 Physiologic groups of microbes in soil, incubated with and without composted rice straw, fertilized with ammonium sulfate.

Organic S mineralizers	0	0	9	0

Source: From Inamatsu^[14] and Primavesi.^[5]

is stored by photosynthetic or chemosynthetic activity of the producer organisms as organic substances, food for the food web.^[3] The BCC considers also, e.g., the feeding capacity of grazing animals (0.5 or 6 animal units of 450 kg live weight/ha yr) or grain equivalent available for humans (4 or 16 persons/ha yr, with a minimum need of 1000 cal/day), calculated as available digestive energy or calories per surface unit and year. The BCC depends on the recovering capacity of a site to produce biomass, after yield, extraction, degradation, or pollution activities. Considering the exuberant flora and biomass production by the Amazonian forest, the following question arises: Which is the BCC of the mostly sandy soils in the Amazonian basin without that vegetation and the aggregated or dependent mesoclimate? Something similar to the Sahara? This example shows that the BCC may be managed in a certain range and sustainability improving the tripod WSB. Considering that the main objective of all human activity, from global to local scale, is to promote life and its quality, mainly the human one, the key tool in the economic system, as a producer and a consumer, the environmental

sustainability will be reached when the BCC is adequate to supply the minimal health life requirements of a given human population. The increase in the BCC level will allow a rise in the human population density. What is occurring is the destruction of the main natural resources—the decrease in the BCC with an increase in the human population density. If nothing is carried out to revert and/or prevent such destruction, then a global disaster with acute local consequences is possible.

CONCLUSION

Looking for the macroscale procedures nature uses to develop the BCC of a sustainable site and its sustainability implications, it could be seen that the increase of resident water, the production or restoration of a surface-protected permeable soil, and the development of a diversified flora and fauna are reflected on the whole biodiversity of the soil macro-, meso-, and microlife and the soil–plant complex. These procedures, based on ecological principles, need to be globally forwarded/passed to the whole human population through formal and informal environmental education programs, to increase the awareness of their vital tie to the environment and to the need to improve or maintain its health to guarantee life and its quality for the existing and future generations.

Bioenergy Crops: Carbon Balance Assessment

Rocky Lemus

Abstract

Bioenergy crops are perennial crops with the potential to sequester carbon (C) into the biomass and soil while providing an alternative source of energy. The decrease in crop productivity due to soil degradation and the increased risks of global warming warrant assessing alternative sources of energy produced on degraded soils. New strategies to mitigate atmospheric carbon dioxide by increasing soil organic matter and biomass productivity are some of the alternatives through bioenergy crops.

OVERVIEW

Since the 1990s, several species have been assessed as potential energy sources and for carbon (C) sequestration. Switchgrass (*Panicum virgatum* L.), a herbaceous species, and two short-rotation woody crops (SRWCs), namely hybrid poplar (*Populus* spp.) and willow (*Salix* spp.), are promising for C sequestration and biofuel production. Using these species as energy crops can partly offset carbon dioxide (CO₂) emitted by fossil fuel combustion.

There are approximately 60 million ha of degraded soil (severely eroded and mined land) in the United States that can be sown to bioenergy crops to decrease soil erosion and increase C sequestration.^[1] The Midwest and the Southeast regions of the United States are the potential areas where bioenergy crops are most likely to compete with other traditional crops for land resources.^[2] The use of bioenergy crops in these areas offers an opportunity to replenish the soil organic C (SOC) pool depleted by tillage and soil degradation.

Biomass fuels used in a sustainable manner can result in no net increase in atmospheric CO₂. Indeed, sustainable use of biomass can result in a net decrease in the rate of enrichment of atmospheric CO₂. This is based on the assumption that all the CO₂ emitted by the use of biomass fuels is absorbed from the atmosphere by photosynthesis. Increased substitution of fossil fuels with biomass-based fuels reduces the risk of global warming by enrichment of atmospheric CO₂. This entry discusses the importance of energy crops in offsetting fossil fuel combustion through C sequestration in biomass and soil.

INFLUENCE OF BIOENERGY CROPS AT THE TEMPORAL SCALE

Long-term tillage and continuous cropping can reduce SOC pool^[3] and increase atmospheric concentration of CO₂ (Fig. 1).^[4] The conversion of natural to agricultural ecosystems results in the net release of C into the atmosphere.^[5] Conservation practices, such as the introduction of perennial crops on degraded agricultural soils and growing bioenergy crops, constitute a direct link between sink (SOC) and the source of CO₂ (fossil fuel). Bioenergy crops are the sink/source transition because the C incorporated into their biomass and root system has a high potential of being incorporated into the soil organic matter (SOM) pool. Most of the C is incorporated into the biomass and soil by the deep and extensive root systems. The SOC pool attains a new equilibrium after grassland restoration, but the time required for SOC to reach equilibrium is variable, especially under diverse climatic conditions.^[6] Most models used to estimate C sequestration in bioenergy crops suggest that a period longer than 10 years may be necessary for pronounced soil-quality improvements.

BENEFITS OF BIOENERGY CROPS

The SOC pool and its dynamics are the major indicators of soil quality and crop productivity.^[7] Bioenergy crops can improve soil quality through increase in SOM, nutrient dynamics, erosion control, and improvement in soil structure and porosity. Most perennial crops and SRWCs have extensive root systems that reduce soil erosion and non-point-source pollution.

Fig. 1 Influence of bioenergy crops on C sequestration and CO₂ mitigation with changes in agricultural practices.
Source: Adapted from Janzen, Campell, et al.^[8]

A shift from traditional agricultural crops into perennial bioenergy crops stabilizes agricultural soils, reduces erosion, and improves water quality.^[9] Most of these benefits are due to the elimination of tillage leading to a significant decrease in both erosion and chemical runoff especially nitrate (NO₃-N). Soil erosion and nitrate runoff are reduced in 2-year-old stands of switchgrass when compared to no-till corn (Table 1). Conservation effectiveness of switchgrass is attributed to high root biomass, which stabilizes the soil,^[10] depletes excess nitrogen (N) and phosphorus,^[11] and increases microbial activity.^[12]

POTENTIAL OF C SEQUESTRATION

Bioenergy crops have the potential to store large quantities of C. Exploring their biomass potential through N fertilization and soil management are some of the proposed strategies to offset CO₂ emissions by fossil fuel combustion. However, a bioenergy crop is not a closed system, and only some portion of the C sequestered might be conserved through the production–utilization cycle. Most of the C sequestered in the biomass is utilized for energy production, allowing some C release back into the atmosphere.

This system does not cause negative impacts, as most of the C returned to the atmosphere is recaptured by the plants during the subsequent season.

Assessing the net C sequestration of bioenergy compared to agricultural crops requires analyses of C sequestration across the soil profile. C sequestration is influenced by biological processes, such as root biomass and crop species, and by soil physical and chemical aspects, such as texture, bulk density, and pH. The amount of C in these types of management options is affected by soil perturbation which could increase SOM oxidation, exacerbating losses, especially at the soil surface. The estimations of C sequestration on land under the Conservation Reserve Program have ranged from 0.6 to 1.0 Mg C ha⁻¹ yr⁻¹ in SOM,^[13] compared to 2.0 Mg C ha⁻¹ yr⁻¹ in SRWC.^[14] Root biomass and its relationship to SOC are always positive but may be influenced by soil depth and plant species.^[15] Switchgrass improves soil quality via reduced nutrient loss (especially NO₃-N) and increases C sequestration through its deep rooting system, high biomass production, and perenniality.^[16] Switchgrass root biomass can be as high as 16.8 Mg ha⁻¹ up to 3.3 m deep with some root mass variability among soil type.^[12]

The sustainability of soil and crop systems is typically affected by changes in the SOC pool. The largest gain in SOC pool occurs in the upper 30-cm layer. There are differences in the amount of C being sequestered by herbaceous crops and SRWCs, but they have the potential to increase C both in the soil and aboveground biomass. The data in Fig. 2 show that after 5 years SOC pool at 60-cm depth was 97.5 Mg ha⁻¹ under willow, 80.5 Mg ha⁻¹ under switchgrass, and 78.5 Mg ha⁻¹ under corn. The mean rate of SOC sequestration, vis-à-vis corn, over 5 years was 3.8 Mg C ha⁻¹ yr⁻¹ under willow and 0.4 Mg C ha⁻¹ yr⁻¹ under switchgrass (Fig. 2). The SOC fluctuations are more drastic in the topsoil layers probably because of the greater effect of precipitation, soil temperature, larger root biomass, and greater microbial activity.

CONCLUSION

Bioenergy crops can influence the global C cycle. An important challenge in using bioenergy crops is assessing how

Table 1 Environmental benefits of switchgrass (SWG) compared to no-till corn (NTC) overtime.

Year	Soil erosion			Water runoff			Nitrate concentration		
	SWG (Mg ha ⁻¹)	NTC (Mg ha ⁻¹)	Ratio SWG/NTC ^a	SWG (Mg ha ⁻¹)	NTC (Mg ha ⁻¹)	Ratio SWG/NTC	SWG (ppm)	NTC (ppm)	Ratio SWG/NTC
1	2.80	0.70	4.00	10.70	2.60	4.11	3.41	0.57	5.98

Source: From Mehdi, Zan, et al.^[18]

much C is being sequestered and how much is being put back into the atmosphere by the co-firing process to produce electricity or other sources of energy. Available data indicate that perennial crops are moving in the right direction in improving soil quality while providing an alternative energy source. A combination of soil C sequestration and bioenergy crops with high biomass capability and deep perennial root systems is a useful strategy of reducing the rate of enrichment of atmospheric CO₂. The use of bioenergy crops increases soil C and improves soil quality by eliminating C losses associated with annual cultivation. However, these improvements depend on the rate of soil C additions, the long-term capacity of the soil for C storage, and the stability or permanence of the sequestered C overtime.

Biofuels versus Agricultural Soils

David Pimentel

Department of Entomology, Cornell University, Ithaca, New York, U.S.A.

Abstract

The rapidly growing world population and rising consumption of biofuels are increasing demand for both foods and biofuels. This exaggerates both food and fuel shortages and increases soil erosion. Using food crops such as corn grain to produce ethanol raises major agricultural, nutritional, and ethical concerns. Nearly 60% of humans in the world are malnourished, so the need for grains and other basic foods is critical. Growing crops for fuel squanders land, water, and energy resources vital for the production of food for human consumption.

INTRODUCTION

The world population is adding a quarter million people each day to the 6.7 billion people who are already present. Soon, it will increase to 13 billion humans on earth. Along with diverse human activities, industrial and transportation development are removing land and other basic resources that provide us with our food, water, and energy.

Conserving land for crops and livestock must become a priority to ensure a sustainable food supply now and for the future, as the world population continues to increase. The protection of farmlands is complicated by the government interest in converting corn crops and ultimately grassland into ethanol.

This entry focuses on conserving land essential for crops, pastures, and forests. Following is an evaluation of how the proposed conversion of biomass crops for ethanol production could impact the U.S. agricultural system and our valuable environmental resources for the future.

CONSERVING SOIL

More than 99% of our food (calories) comes from the land while less than 1% comes from the oceans and other aquatic ecosystems. Therefore, maintaining fertile cropland must be a primary concern of all who wish to ensure a sustainable food supply for humans and wildlife now and for the future.

Wind and rain displace and remove layers of topsoil and diminish the nutrients and the water holding capacity of the soil; this, in turn, reduces the productivity of the soil. A ton of fertile topsoil averages 1–6 kg of nitrogen, 1–3 kg of phosphorus, and 2–30 kg of potassium, whereas the soil on eroded land has average nitrogen levels of only 0.1–0.5 kg/t.^[1] Eroded soil carries away vital plant

nutrients such as nitrogen, phosphorus, potassium, and calcium. Typically, the eroding soil contains about three times more nutrients than are left in the remaining soil.

When soil nutrient resources are depleted by erosion, plant growth is stunted and overall productivity declines.^[2,3]

Nutrient deficient soils produce 15–30% lower crop yields than uneroded soils.

Land areas covered by plant biomass, living or dead, are protected and experience relatively little soil erosion because raindrops and wind energy are dissipated by the biomass layer. For example, in Utah and Montana, as the amount of ground cover decreased from 100% to <1%, erosion rates increased ~200 times.

On average, the soil erosion rate on U.S. cropland is about 10 t/ha/yr.^[4] However, these rates of erosion greatly exceed the average rate of natural soil formation from the parent material. Under agricultural conditions, soil formation ranges from 0.5 to 1 t/ha/yr.^[5,6] Thus, U.S. cropland is losing soil more than 10 times faster than its replacement rate.^[4]

In the United States, soil erosion is severe on some of the most productive agricultural ecosystems. For instance, one half of the fertile topsoil of Iowa has been lost by erosion during the last 150 years of farming. These high rates of erosion continue there at a rate of about 30 t/ha/yr both because of the rolling hill topography and type of agriculture practiced.^[7] Similarly, 40% of the rich soil of the Palouse region in the northwestern United States has been eroded during the past years of cultivation. In both of these regions, intensive agriculture is employed and monocultural plantings are common. Also, many such areas are left unplanted during the late fall and winter months, further exposing the soil to erosion. Yearly in the United States, several thousand hectares of once valuable cropland are abandoned, because rain and wind erosion have made them unproductive.

To offset some of the nutrient losses caused by erosion, large quantities of fossil-based fertilizers often are applied.

If the soil base is relatively deep, about 300 mm, and if only from 10 t to 20 t of soil is lost per hectare per year, the lost nutrients can be replaced with the application of commercial fertilizers and/or livestock manure.^[2,3] For example, of the ~900 L of fossil energy required to produce 1 ha of corn, about 300 L of this energy is for fertilizers.^[8] However, this replacement strategy is expensive for the farmer and nation and usually not affordable by poor farmers. The estimate is that the lost soil nutrients cost U.S. agriculture \$10–\$20 billion annually. Furthermore, not only are the fertilizer inputs fossil-energy dependent, these chemicals can harm human health and pollute the environment.^[9]

Soil erosion in the United States is reported to cause \$45 billion in environmental and public health impacts each year.^[2] Removing about half of the biomass, including all crop residues, would intensify the soil loss and more than double the economic losses from soil erosion to >\$100 billion per year.

Although erosion rates on U.S. cropland have decreased during the past decades, erosion rates on rangelands remain relatively high or about 6 t/ha/yr.^[9] Such high erosion rates are typical on more than half of the world's rangelands including those in the United States. Soil erosion on U.S. pastures and rangelands is having a negative impact on livestock production, which relies on pasture grasses.

BIOFUEL PRODUCTION

Basic to producing all biomass (food crops, including corn, sugarcane, soybeans, and cereal grains) are large land areas, water supplies, and fossil energy. For ethanol and biodiesel production, these resources are used both in the production of the biomass and subsequently in the processing of the biomass to produce ethanol or biodiesel.

To guarantee increased production of corn ethanol, the U.S. government spends about \$6 billion in subsidies. The corn ethanol subsidies per gallon are 60 times greater than the subsidies per gallon of gasoline!

For ethanol production, vast quantities of corn must be grown. Twenty-two pounds of corn are required to produce one gallon of ethanol. A total of 1700 gal of water is required to produce 1 gal of ethanol. Water use for ethanol processing plants is draining aquifers that support some local communities. Especially, large quantities of water are required for corn production. In the United States, corn production uses 5,600,000 L of water per hectare in one growing season. If irrigation is necessary, about twice that amount is required. Each gallon of ethanol produced also creates about 12 gal of sewage effluent that must be discarded into the local sewage system. Another challenge is that the ethanol must most often be transported by truck and/or rail.

Pimentel and Patzek report (2007) that 46% more fossil energy is required to produce 1 L of ethanol from corn than

the energy in the ethanol;^[8] in contrast, some in the U.S. Department of Agriculture (USDA) report anywhere from a 21% to a 64% net return in corn ethanol.

Because corn is a food for cattle, hogs, and chickens, livestock producers are faced with increased costs and the consumer is faced with increased prices of milk, meat, and eggs. In addition, over many decades U.S. corn has been a staple food for many poor people in the world.

In 2006, the United States is producing 5 billion gallons of ethanol, and this production is using 20% of all U.S. corn and represents only 1% of U.S. petroleum use. If 100% of U.S. corn were to be used, it would provide only 7% of U.S. petroleum use (Table 1).

The USDA reports a 50% greater return using corn stover to produce ethanol than using only the corn grain. This is extremely surprising, when it is known that corn stover has only half of the starches and sugars that corn grain has. In addition, to release the starches and sugars held in the lignin in the corn stover, either an acid or special enzyme is needed to dissolve the lignin.^[8]

Perlack et al. claim that 1.5 billion tons of biomass can be harvested each year from U.S. land and converted into biofuels providing the nation with 30% of its liquid fuel needs.^[10] This suggests that one half of the 3 billion tons of all biomass (such as crops, forests, and grasses) produced annually in the United States can be utilized. No consideration was given to the further needs of agriculture or the needs of wildlife and other organisms. Under growing pressure to replace dwindling fossil-fuel supplies, focus is on grassland and forest biomass to produce ethanol. Tilman, Hill, and Lehman^[11] and Perlack et al.^[10] recommend the harvesting of crop residues such as corn stover for the biofuels program. This would be especially disastrous for agricultural ecosystems. Note that there are 100 million cattle, 7 million sheep, and 4 million horses grazing on grasses—what will these livestock be fed if all or most of the grass is used for cellulosic ethanol?

Without the protection of crop residues such as corn stover, soil loss in crop production would increase from 10-fold to 100-fold. Already the U.S. crop system is losing soil 10 times faster than sustainability.^[9] Soil formation rates are extremely slow, ranging from 0.5 to 1.0 t/ha/yr.^[1,9] Increased erosion will facilitate soil carbon oxidation and contribute to the greenhouse problem.^[12]

Table 1 Energy inputs and outputs of some U.S. biofuels per liter of 99.5% ethanol or biodiesel.

Crop	Input (kcal/L)	Output (kcal/L)	Gain or loss (%)
Corn	7,474	5,130 (ethanol)	−46
Switchgrass	8,634	5,130 (ethanol)	−68
Sugarcane	4,578	5,130 (ethanol)	+04
Soybean	12,564	9,000 (biodiesel)	−40

Source: From Pimentel & Patzek.^[8]

Such an intensification of the U.S. soil erosion problem would significantly reduce not only corn, but also other crop production.^[1] Corn production already causes more soil erosion than any crop produced in the United States.^[9] Removing most of the corn stover, or any other crop residues, would devastate corn and all other crops, especially row crops. Note that soil loss from row crops, such as corn and soybeans used as biofuels, is about 50 times higher than the soil erosion rates with sod-type crops, such as pastures.

CONCLUSION

The continued expansion of biomass for ethanol production will devastate vast land areas and expose more soil to erosion. Based on existing biomass production and processing methods, the ethanol produced will not make the U.S. oil independent. Meanwhile, billions of government funds are being spent to encourage ethanol production.

The conversion of millions of hectares of land for biomass and ethanol production is doing long-lasting damage to vital soil and water resources of the United States.

Biological Crusts

Jayne Belnap

Southwest Biological Science Center, U.S. Geological Survey (USGS), Moab, Utah, U.S.A.

Abstract

Desert soil surfaces are generally covered with biological soil crusts, a group of organisms dominated by cyanobacteria, lichens, and mosses. Despite their unassuming appearance, these tiny organisms are surprisingly critical to many processes in past and present desert ecosystems and are vital in creating and maintaining fertility of desert soils. They fix both carbon and nitrogen, much of which is leaked to the soils below. They stabilize soils, capture nutrient-rich dust, and can stimulate plant growth. These organisms must tolerate extreme temperatures, drought, and solar radiation, despite having relatively few wet hours for metabolic activity. Under most circumstances, they are extremely vulnerable to climate change and disturbances such as off-road vehicles and livestock grazing. Unfortunately, recovery times are generally measured in decades or centuries.

INTRODUCTION

Biological soil crusts (BSCs; Fig. 1) are a community of cyanobacteria, microfungi, lichens, or mosses that occur on the soil surface in most dryland and subhumid regions as well as in other ecosystems where light can reach the soil surface (e.g., treefall gaps and pine barrens; see the review by Belnap and Lange^[1]). Well-developed BSCs can dominate the living cover in dryland regions and can contain more diversity than the surrounding vascular plant community. The external morphology of BSCs is determined by climate and species composition, with four main types being recognized (Fig. 2); cyanobacterially dominated *smooth crusts* are found in hyperarid regions [no frost heaving, very high potential evapotranspiration (PET)]. *Rugose crusts*, with a microtopography <3 cm, are found in arid deserts (no frost heaving, high PET, and very low moss–lichen cover). *Pinnacled crusts* occur in semiarid cool deserts (moderate PET, lichen–moss cover <40%, and freezing soils) and have a microtopography of up to 15 cm. *Rolling crusts* are found in semiarid cool/cold deserts (low PET, freezing soils, and >40% lichen–moss cover), but the cohesion of the high moss–lichen cover restricts the pinnacles to <5 cm. The external morphology of BSCs is very important, as it influences how and whether materials such as dust, water, organic matter, and seeds move across or are retained by the soil surface.

The desert soil surface is one of the most extreme environments on earth. Temperatures can range from –20°C to +70°C. Solar radiation is high, and rainfall is infrequent and sparse. The key to survival for BSC organisms is their ability to desiccate and terminate or slowdown the metabolic processes. In addition, many BSC species photosynthesize at

high and low temperatures, have high water-holding capacities, require only low amounts of moisture to begin metabolic activities, and can cope with high radiation loads. Many BSC taxa are similar around the world, despite their occurrence in a wide range of climates and vegetation types. Unrelated taxa often have comparable structures, implying that soil surface conditions have produced convergent evolutionary trends.

Biological crusts perform many critical roles in the ecosystems in which they occur. Well-developed, late successional BSCs (supporting lichens and mosses) are better able to perform the functions discussed below than BSCs kept at an early successional stage by climate or disturbance.

WEATHERING

BSCs increase water retention, thus enhancing freeze–thaw action and the dissolution of minerals in rocks. The metabolic activities of BSCs increase soil pH approximately by 2 pH units (e.g., ~8 to ~10.5), accelerating weathering rates of siliceous rock by up to 100 times.^[2]

SOIL PHYSICAL STRUCTURE AND STABILIZATION

Polysaccharides extruded by BSCs and the anchoring structures of mosses and lichens bind soil particles together and form soil aggregates (Fig. 3). Soil aggregates enhance soil nutrient transformation rates, soil aeration, and gas/water movement. In addition, BSCs greatly increase the resistance of soils to wind and water erosion.^[3,4]

Fig. 1 (A) Soil crusts cover the large interspaces between vascular plants. (B) Close-up view shows crust mounds that greatly roughen soil surfaces, enhancing retention of water, organic matter, dust, and seeds.

SOIL–WATER RELATIONS

In smooth and rugose crusts, BSC organisms reduce surface porosity while not substantially enhancing surface roughness; thus, they reduce water infiltration. In contrast, pinnated and rolling BSCs greatly roughen the soil surface and thus increase water infiltration. On heavy clay soils, BSCs have little effect on infiltration. Because of these differences, data on the effect of BSCs on soil water relations are conflicting, and more work is needed.^[5]

ALBEDO

Biologically crusted surfaces decrease surface energy flux by up to $\sim 40 \text{ J m}^{-2} \text{ s}^{-1}$, increasing dry surface temperatures by 10–14°C.^[1] Surface temperatures regulate many ecosystem functions, including rates of nitrogen and carbon fixation, microbial activity, plant nutrient uptake and growth, evaporation, and seed germination. The timing of these events is often critical for desert plants, and relatively small alterations can affect community structure. In addition, many animals depend on temperature to regulate their foraging times and burrowing depths.

SOIL FERTILITY AND VASCULAR PLANTS

The increased surface roughness and sticky polysaccharide sheaths exuded by BSCs increase the capture of dust, enriching soil nitrogen, phosphorus, potassium, and (depending on the original soil texture) water-holding capacity.^[6] In addition, the negatively charged polysaccharides reduce leaching by binding nutrients, especially cations. Biological crusts secrete chelating compounds,

(C) Cyanobacterial filaments increase soil aggregate structure. (D) Close-up view of a soil surface, sliced vertically. Note the spider web-like cyanobacterial fibers holding the soil aggregates in place.

which are important for keeping metals bioavailable in high pH soils. BSCs also contribute nitrogen ($1\text{--}10\text{ kg yr}^{-1}\text{ ha}^{-1}$) and carbon ($1\text{--}37\text{ g m}^{-2}\text{ yr}^{-1}$) to soils, much of which is released from BSCs upon wetting and utilized by nearby plants, fungi, actinomycetes, and bacteria. Soil fauna are more diverse and abundant in BSC-covered soils.^[1]

Smooth and rugose BSCs generally increase movement of seeds, water, and organic matter from plant interspaces to nearby obstacles (e.g., rocks and plants), whereas pinnated and rolling crusts can increase the retention of materials in the interspaces between plants. Most studies show BSCs enhance or do not affect native seed germination, whereas they retard germination of at least some exotic annual grasses in many ecosystems. As BSCs cannot compete for light with vascular plants, BSC cover is reduced with greater plant cover.^[1]

THE RESISTANCE AND RESILIENCE OF BSCS

Many existing and future conditions threaten BSCs, including soil surface disturbance, increased temperatures, exotic annual grass invasions, and increased fire.^[1] Although BSCs are highly tolerant of stresses with which they evolved (e.g., radiation and drought), they have little resistance to the compressional forces generated by livestock or human activities. These forces essentially pulverize the BSCs, with lichens and mosses being the most susceptible to loss. Annual grasses occupy the plant interspaces once covered by BSCs, reducing BSC cover. Rodents and increased fire that accompany annual grasses also lead to a reduction in BSC cover. As millions of hectares of rangelands are dominated by exotic annual grasses, we stand to lose large amounts of well-developed lichen–moss BSCs throughout deserts of the world.

All BSCs are metabolically active only when wet, and their rates of physiological functioning are highly responsive to temperature. Existing climate models predict higher temperatures and altered precipitation patterns, which will affect the structure and function of BSCs. Increased summer rain will very likely increase carbon deficits in BSCs, as they will dry too quickly to replace respired carbon. Less winter rain will reduce carbon gain. Less carbon gain translates into less nitrogen fixation, as this process requires photosynthetic products, and, together, these decreases will reduce soil fertility. With reduced access to adequate carbon and nitrogen, crusts will be less able to avoid or repair radiation damage, increasing mortality and most likely altering the existing species distribution patterns.

Recovery rates depend on the availability of inoculant (natural or cultured, in the case of cyanobacteria) and on the characteristics of the site, including soils, climate, and disturbance. In coarse soils with low stability, fertility, and water-holding capacity, BSCs recover more slowly than when on fine-textured soils. On stable soils (e.g., low slope, low wind deposition of sand, and embedded rocks), BSCs recover faster than on less stable sites (e.g., steep slopes, high sand deposition, and rolling rocks). Because BSC organisms are metabolically active only when wet, microhabitats (e.g., shrub canopies) and regions with lower PET recover more quickly than drier places. When disturbance is severe or frequent enough to remove crust material, recovery is slower than if organisms are crushed but left in place.

Cyanobacteria recolonize most rapidly. The larger, filamentous cyanobacteria (e.g., *Microcoleus vaginatus*) appear first. Once they stabilize soils, the less mobile and smaller cyanobacteria and green algae appear. In regions where PET is low enough, early successional lichen and moss species appear next (e.g., the cyanolichen *Collema*).

As PET decreases further, mid- and late successional desert lichens, most with green algal phycobionts, colonize next. Recolonization of these later successional species can be very slow, especially if disturbed areas are large. In regions with low PET, recovery can be fairly fast (20 years), while recovery in high PET regions can be extremely slow (1000+ years). Intact crust material salvaged from one area and reapplied to another has long been used to speed recovery in small areas. Growth of cyanobacterial inoculant and application in the field have been attempted for some time. While there are several successful methods for growing the cyanobacteria, past field applications have not been overly successful.^[7] However, techniques developed in China show great promise.^[8]

CONCLUSION

Soil fertility and stability are heavily influenced by BSCs, especially in dryland environments. Unfortunately, many human activities are incompatible with their well-being. The cyanobacteria fibers that confer such tensile strength to soils cannot withstand the compressional stresses generated by animals or vehicles. Exotic annual grasses and increased fire often follow surface disturbance, further threatening BSCs. Compromised crusts contribute less to soil fertility and are less able to offer protection from wind or water erosion. Unlike vascular plant cover, biological crust cover is not reduced in drought, and unlike physical soil crusts, they are present under all soil moisture conditions. Consequently, biological crusts, over time and under adverse conditions, offer many services to ecosystems that are often low in resources. For more information, see www.soilcrust.org.

Biological Nitrogen Fixation

Robert H. Burris

Department of Biochemistry, College of Agriculture and Life Sciences, University of Wisconsin, Madison, Wisconsin, U.S.A.

Abstract

The symbiotic process of nitrogen (N_2) fixation by leguminous plants plus associated root nodule bacteria (*Rhizobium* species) is of the greatest practical importance to agriculture, but there are also a number of free-living bacteria capable of N_2 fixation. There are well over 10,000 legume plant species that fix N_2 and about 200 nonlegumes.

INTRODUCTION

For centuries farmers practiced mixed cropping of leguminous and nonleguminous plants without knowing the basis of the empirically observed benefit from the practice. The first clear recognition that leguminous plants could utilize nitrogen (N_2) from the air is attributed to Boussingault's report in 1838.^[1] Skepticism remained until Hellriegel and Wilfarth in Germany in 1886 reported definitive experiments demonstrating that pea plants (*Pisum sativum*) in association with bacteria borne in their root nodules were capable of utilizing N_2 .^[1]

SYMBIOTIC AND FREE-LIVING N_2 FIXERS

The symbiotic process of N_2 fixation by leguminous plants plus associated root nodule bacteria (*Rhizobium* species) is of greatest practical importance to agriculture, but there are also a number of free-living bacteria capable of N_2 fixation. The first of these recognized was the anaerobic organism *Clostridium pasteurianum* as reported by Winogradsky in 1893.^[2] In 1901, Beijerinck recorded that the aerobic bacterium *Azotobacter chroococcum* also fixed N_2 .^[2] These early observations were followed by practical applications, and the practice of inoculation of leguminous seeds with cultures of the rhizobia became widespread. The bacteria were grown commercially and farmers applied these bacteria to leguminous seeds at the time of planting. There is a specificity between the plants and bacteria, and this gave rise to the recognition of cross-inoculation groups, i.e., groups of plants all of which are nodulated by the same species of rhizobia. For example, *Rhizobium leguminosarum* infects garden peas, sweet peas (*Lathyrus odoratus*), common vetch (*Vicia faba*), hairy vetch (*Vicia villosa*), and lentil (*Lens culinaris*), whereas *Rhizobium japonicum* is rather specific for soybeans (*Glycine max*). Not all strains of root nodule bacteria that infect a plant are equally

effective in N_2 fixation, and this is referred to as strain variation. Because of strain variation, commercial inoculants often are a mixture of effective strains. Inoculants are grown as large batches of effective organisms in liquid culture, and then, these cultures are mixed on a peat base. The finely ground peat retains moisture, and the microorganisms remain viable for long periods. The peat culture is mixed with seeds before planting, and the viable organisms are in proximity when the seeds germinate and produce roots. The bacteria induce curling of root hairs and invade the plant through the root hairs. After invasion, they induce the production of root nodules and proliferate in the nodules. The bacteria undergo morphological and metabolic changes in the nodule and are referred to as bacteroids. Bacteroids in the nodule are capable of fixing N_2 from the air.

Claims of fixation of N_2 by cultures of the rhizobia outside the host plant in general could not be verified. In 1975, three laboratory groups reported success in achieving such fixation, by furnishing succinic acid as the substrate for growth and by culturing the organisms under a very low pressure of oxygen.^[3]

The rhizobia function at a low oxygen concentration in the nodule. The nitrogenase enzyme system is labile to oxygen, but there must be sufficient oxygen to support the generation of adenosine triphosphate (ATP). Hemoglobin in nodules achieves this necessary balance in the oxygen level, keeping it adequate to support the action of cytochrome oxidase that generates ATP.

There are well over 10,000 legume plant species that fix N_2 and about 200 nonlegumes. Only one of these nonlegumes has been reported to be nodulated by a *Rhizobium* species such as nodulate the legumes: this is *Parasponia andersonii*, a tree of the elm group. The other nonleguminous plants, such as the alder (e.g., *Alnus glutinosa*), fix N_2 in association with actinomycetes. It proved extremely difficult to culture these actinomycetes, but since methodology to isolate and culture these organisms was

developed in 1977,^[3] information on them has expanded substantially. Some of the actinorhizal associations have found extensive use, particularly in tropical and low-rainfall areas.

BIOCHEMISTRY OF N₂ FIXATION

Early studies on biological N₂ fixation emphasized the practical applications of the process and the development of effective inoculants. Since 1925, there has been interest in the biochemistry of the N₂ fixation process. Wilson^[1] utilized nodulated red clover plants (*Trifolium pratense*) to demonstrate that half-maximum fixation occurred at a pN₂ (partial pressure of N₂) of about 0.05 atmosphere (approximately 50 millibar). High levels of O₂ inhibited the fixation non-competitively. While growing clover plants under controlled atmospheres, Wilson^[1] made the unexpected observation that fixation was inhibited by hydrogen (H₂) gas. H₂ is a specific and competitive inhibitor of N₂ fixation. The H₂ inhibition of N₂ fixation results from an ordered, sequential process in which the H₂ must bind to the nitrogenase enzyme before the N₂.

There was speculation about the first or key product of N₂ fixation. Winogradsky^[2] suggested that ammonia (NH₃) was the first product. Virtanen,^[2] on the other hand, supported hydroxylamine as the key intermediate based on his claim that leguminous plants excreted aspartic acid and that the hydroxylamine formed by fixation reacted with oxaloacetic acid to form an oxime that then was converted to aspartic acid. Other investigators failed to confirm Virtanen's work. The use of the stable isotope ¹⁵N as a tracer resolved the argument. ¹⁵N-enriched N₂ was supplied to a culture of *Azotobacter vinelandii* fixing N₂ vigorously, and among the amino acids recovered from the hydrolysate of the cells, the highest enrichment in ¹⁵N among the isolated amino acids was in glutamic acid^[2] rather than in aspartic acid, which would have been supportive of Virtanen's hydroxylamine hypothesis. If NH₃ were the key product of fixation, it could logically be incorporated into glutamic acid by the action of known enzymes. Similar experiments were performed with species of bacteria from the genera *Clostridium*, *Chromatium*, *Chlorobium*, and *Rhodospirillum*, as well as the blue-green alga *Nostoc muscorum* and excised soybean nodules. In all cases, the highest concentration of ¹⁵N among the isolated amino acids was in glutamic acid.

CELL-FREE N₂ FIXATION

As the metabolism of nitrogenous compounds in intact microorganisms can be rather complex, it was important to verify the path of fixation in cell-free preparations where reactions can be defined more specifically. ¹⁵N as a tracer furnished a sensitive tool for seeking reliable cell-free fixation. Carnahan and coworkers in 1960^[3] developed a

method for recovering active preparations consistently from *C. pasteurianum*. Such cell-free preparations supplied ¹⁵N-enriched N₂-yielded NH₃ with over 50 atom% ¹⁵N excess, a very convincing verification that NH₃ is the "key" intermediate in biological N₂ fixation.

PURIFICATION OF NITROGENASE

Mortenson^[3] demonstrated that the cell-free enzyme system consisted of two proteins. When the two proteins were purified, it turned out that one component was a molybdenum-iron (MoFe) protein, and the other was an iron protein. In purification on a chromatographic column, the MoFe protein was eluted before the Fe protein, so the MoFe protein was often referred to as protein 1 or component 1 and the Fe protein as protein 2 or component 2. A number of other terminologies were used but abandoned. Descriptive terms are dinitrogenase for the MoFe protein, dinitrogenase reductase for the Fe protein, and nitrogenase for the complex of the two components. The primary function (it also has other functions) of the Fe protein is to transfer electrons to the MoFe protein and hence the designation dinitrogenase reductase.

REQUIREMENT FOR ATP

In 1960, it was reported that ATP was inhibitory to N₂ fixation in cell-free preparations of nitrogenase, but in 1962 McNary^[3] demonstrated that ATP is an absolute requirement for fixation by such preparations. The N-N bond is stable, so N₂ fixation is energy demanding whether it is accomplished chemically at high temperature and pressure or whether it is accomplished by a biological system. A minimum of 16 ATPs are required for the reduction of one N₂ to 2NH₃. Sixteen ATPs are required under ideal conditions, and the requirement is 20 to 30 ATPs under the most conditions in nature.

SUBSTRATES OTHER THAN N₂

Nitrogenase is a versatile enzyme and is capable of reducing substrates other than N₂.^[3] It was recognized early that H₂ is a by-product of the nitrogenase reaction. The next substrate to be recognized was nitrous oxide that is reduced to N₂. Cyanide, methyl isocyanide, and azide can also be reduced by the enzyme system. Nitrogenase can reduce acetylene to ethylene. Other substrates demonstrated include diazine, diazirine, cyanamide, and cyclopropene. Acetylene reduction to ethylene has become a widely used measure of nitrogenase activity. The substrate is easy to prepare, the ethylene formed as a product can be measured readily and accurately by gas chromatography, and the simple method has been applied to studies in the glasshouse and field.

CONTROL OF NITROGENASE

As N_2 fixation is energy demanding, it is advantageous for the fixing organisms to turn off the system if they have access to a source of fixed N_2 . Ludden^[3] found that *Rhodospirillum rubrum* turned its nitrogenase off when supplied fixed N_2 such as NH_3 or when it was placed in the dark and thus was deprived of light energy. When NH_3 was exhausted or when light was restored, it turned nitrogenase back on. Inactivation is achieved by ADP ribosylation of arginine 100 of one of the two equivalent subunits of dinitrogenase reductase, and reactivation is achieved by the removal of this ADP-ribosyl group.

TERTIARY STRUCTURE OF NITROGENASE

The tertiary structure of the nitrogenase components was established in 1992.^[2] This aids one in visualizing how the dinitrogenase and dinitrogenase reductase fit together and how the active Fe and MoFe sites are aligned.

ASSOCIATIVE N_2 FIXATION

The leguminous plants and their associated rhizobia are of great practical importance in agriculture, but the non-leguminous actinorhizal systems often fix N_2 vigorously and occupy important niches in ecosystems. Certain non-legumes can benefit from association with bacteria that

occupy their root surface or multiply within the plant without forming nodules.^[3,4] In Brazil, it has been demonstrated that sugarcane can derive N_2 from fixation by *Acetobacter diazotrophicus* carried inside the cane. *A. diazotrophicus* is a remarkable bacterium, as it can grow in a 25% sucrose solution and fix N_2 at a pH as low as 3.0.

GENETICS OF THE NITROGENASE SYSTEMS

The genetics of biological N_2 -fixing systems has occupied many investigators, as genetic manipulations may offer ways to improve the process or adapt it to new crops. Progress in our knowledge of the genetics of N_2 -fixing organisms has led to a substantial reorganization of classification of these organisms.

Biological Nitrogen Fixation: Contributions to Agriculture

Mark B. Peoples

Plant Industry, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Canberra, Australian Capital Territory, Australia

Abstract

Symbiotic associations between legumes and rhizobia are responsible for the greatest contributions of biological nitrogen fixation (BNF) in agricultural systems. Data collected from pulses, legume oilseeds, and pastures growing in farmers' fields generally indicate the levels of BNF much lower than the potential values observed under experimental conditions. Strategies are available to improve BNF beyond what is being achieved. For example, enormous benefits in terms of crop production and dinitrogen fixed can be derived from the application of good agronomic principles. But the ability to overcome constraints at the farm level may be limited because either the relevant technologies are not in the hands of the farmers, or they cannot readily adopt them because of lack of knowledge and information, economic constraints, or operational imperatives. There are a number of environmental advantages in relying on BNF over fertilizer nitrogen to produce such large quantities of high-quality protein.

INTRODUCTION

Although dinitrogen (N_2) gas represents almost 80% of the earth's atmosphere, it is not a source of nitrogen (N) that is readily available to plants. However, a number of prokaryotic microorganisms have evolved that utilize the enzyme nitrogenase to reduce atmospheric N_2 to ammonia, which can subsequently be used to support their growth. Biological N fixation (BNF) by some diazotrophs can occur in a free-living state, or via associative relationships with plants, while others can fix N_2 only in symbiosis with specific plant hosts.^[1] Although calculations of global contributions of BNF are subject to enormous approximations, annual inputs of fixed N into arable agroecosystems have been conservatively estimated to be 35–55 million metric tonnes of N, with a further 40–45 million tonnes of N per year occurring in permanent pastures.^[2] This compares to 75–80 million tonnes of N applied to crops and grasslands as fertilizer each year.^[2]

SOURCES OF FIXED N IN AGRICULTURAL SYSTEMS

The N_2 fixation process can directly contribute to agricultural production where the fixed N is harvested in grain or other food for human or animal consumption. However, BNF can also represent an important renewable source of N that can help maintain or enhance the fertility of many agricultural soils. Examples of experimental estimates of amounts of N fixed by various N_2 -fixing organisms are presented in Table 1. Values for associative and symbiotic

systems have always been determined from measures of plant shoot biomass. Belowground contributions of fixed N have generally been ignored. However, research suggests that N associated with roots might represent between 25% and 60% of the total N accumulated by crops and pastures.^[3–5] Therefore, total inputs of fixed N could be 50–100% greater than has been traditionally determined from shoot-based measurements, such as those depicted in Table 1.

Contributions by Different N_2 -Fixing Organisms

Free-living N_2 fixers probably contribute only small amounts of N to agricultural systems (Table 1). The data tend to be inconclusive concerning the role of diazotrophs associated with non legumes in temperate agriculture, but studies have demonstrated significant inputs of fixed N by tropical grasses and crops such as sugarcane (*Saccharum officinarum*).^[1,6] Symbiotic associations between legumes and specific soil bacteria (*Rhizobium*, *Bradyrhizobium*, *Allorhizobium*, *Azorhizobium*, *Mesorhizobium*, or *Sinorhizobium* spp.) in specialized root structures (nodules) are generally responsible for the largest amounts of fixed N in farming systems (Table 1).

Inputs of Fixed N by Legumes

BNF by legume systems that play a key role in world crop production is irrefutable. The ability of legumes to progressively improve the N status of soils has been utilized for thousands of years in crop rotations and traditional farming systems.^[1,2,7] The 163 million hectares of legume oilseeds (soybean—*Glycine max*; and

Table 1 Experimental estimates of the amounts of N₂ fixed in different agricultural systems.

N ₂ -fixing organism	Range measured (kg N/ha per crop or per year)	Range commonly observed (kg N/ha per crop or per year)
Free-living		
Crops	0–80	0–15
Associative		
Tropical grasses	10–45	10–20
Crops	0–240	25–65
Symbiotic		
Azolla	10–150	10–50
Green manure legumes	5–325	50–150
Pasture/forage legumes	1–680	50–250
Crop legumes	0–450	30–150
Trees/shrubs	5–470	100–200

groundnut—*Arachis hypogea*) and pulses sown globally each year, legume components of the 200 million hectares under temporary pastures or fodder crops, and the 10–12 million hectares of perennial legume cover crops in rubber (*Hevea brasiliensis*) and oil palm (*Elaeis guineensis*) plantations contribute fixed N to farming systems. Most modern methods used to quantify inputs of fixed N by legumes separate the plant N into fractions originating from soil N or N₂ fixation.^[1,5,8] Once the legume N can be partitioned into that proportion derived from atmospheric N₂ (%Nd_{fa}, sometimes also described as %P_{fix}) and that coming from the soil, the amounts of N₂ fixed can be calculated from measures of shoot dry matter (DM) and N content. The formation of the symbiosis between legume and rhizobia is dependent on many factors and cannot be assumed to occur as a matter of course. This is reflected in the range of values presented in Table 1. Such large variations in reported estimates of N₂ fixation make it difficult to generalize about how much N may be fixed by different legume species. Collectively, the data suggest maximum rates of N₂ fixation of 3–4 kg shoot N/ha/day^[5] and potential inputs of fixed N by many legumes of several hundred kilograms of shoot N/ha each year (Table 1). However, much of the information in Table 1 was derived from research trials in which specific treatments were imposed to generate differences in %Nd_{fa} values and legume growth as an experimental means of studying factors which regulate BNF. Therefore, these data may be of little relevance to what might actually be occurring in farmers' crops and pastures. Fortunately, measurement procedures have been developed which allow on-farm measures of legume N₂ fixation to be conducted with confidence.^[5,7,8]

Levels of N Fixation Achieved in Farmers' Fields

Examples of the types of information which can be generated about BNF in farmers' fields are presented in the tables for farming systems in different regions of the world. These on-farm data and observations can be used to develop a picture of N₂ fixation within an individual country or region and provide insights into contributions of BNF to agriculture on a global scale. Collectively, the results in Table 2 indicate that the potential for BNF inputs can differ between legumes and countries, but they also suggest many commonalities. Although wide ranges in %Nd_{fa} values have been observed, it seems that, on average, most winter pulses (e.g., chickpea—*Cicer arietinum*; lentil—*Lens culinaris*; field pea—*Pisum sativum*; faba bean—*Vicia faba*; and lupin—*Lupinus albus*) relatively satisfy higher proportions of their growth requirements from N₂ fixation (>65%) than do the summer legumes (e.g., mung bean—*Vigna radiata*; mash bean—*Vigna mungo*; soybean; and groundnut) where %Nd_{fa} values were commonly less than 60% (Table 2). Poor or variable nodulation observed in some summer legumes and the resulting increased reliance upon soil N may reflect greater N mineralization during summer, water stress, and/or low vegetative biomass accumulated by short duration legume crops.^[8,9]

Table 2 Summary of the proportion of plant N derived from N₂ fixation (%Nd_{fa}) and the amounts of N₂ fixed by farmers' legume crops and pastures in different geographical regions.

Country and legume	Number of fields	Mean Nd _{fa} (%)	Total N fixed (kg N/ha) ^a
Winter pulse crops			
Pakistan	126	78	79
Nepal	27	79	78
Syria	46	67	na ^b
Australia	90	65	170
Summer legume crops			
Pakistan	63	47	42
Nepal	50	55	77
Thailand	13	75	78
Vietnam	45	48	125
South Africa	14	58	na ^b
Australia	33	53	267
Annual pastures			
Australia	300	75	na ^b
Perennial pastures			
Australia	110	64	na ^b

Note: Nd_{fa}, nitrogen derived from atmospheric N₂.

^aIncludes an estimate of fixed N from the roots and nodules which assumes that belowground N represents 33% of total plant N.

^bData not available for all fields.

Table 3 Key factors influencing inputs of fixed N by legumes in farmers' fields.

Country	System	BNF regulated by		
		DM	Soil nitrate	Primary factors
Pakistan	Winter crop	+++		Rainfall nutrition, weed control
	Summer crop	+++	+++	Fertilizer N, no inoculation, insects, disease
Nepal	Winter crop	+++		Rainfall, nutrition
	Summer crop	+++	+	Total soil N, mineralized N, available P, legume species
Syria	Winter crop	+++	++	Soil nutrients, insects, disease
Thailand	Summer crop	+++		Available P
Vietnam	Summer crop	+++		Plant density, soil pH, available P, legume species
South Africa	Summer crop	++	++	Effective inoculation, nutrition, rotation, water availability
Australia	Winter crop	+++	+++	Rainfall, fallowing, legume species
	Summer crop	++	+++	Crop rotation, tillage, rainfall
	Pasture	+++	+	Soil pH, available P, legume density, grazing management

Note: BNF, biological N₂ fixation; DM, dry matter; P, phosphorus.

In grazed pastures, the competition for mineral N between legumes and companion grasses or vigorous broadleaf weeds growing within the pasture sward results in low levels of plant-available soil N throughout the growing season.^[4,7] As a consequence, %Nd_fa by the legume components of pastures tends to be high (Table 2). The slightly lower %Nd_fa values detected in perennial legume species, such as alfalfa (*Medicago sativa*) and white clover (*Trifolium repens*), presumably result from a greater ability to scavenge soil mineral N from a larger rooting zone compared with annual pasture species.^[4]

Although the levels of %Nd_fa are important, the amounts of N₂ fixed are usually regulated by legume growth rather than %Nd_fa in most farming systems,^[7] and many legumes appear to fix approximately 20 kg of shoot N for every metric ton of shoot DM accumulated.^[4,7,8]

Impact of Management

Factors that either enhance or depress N₂ fixation (Table 3) can generally be summarized in terms of environmental or management constraints to crop growth (e.g., basic agronomy, nutrition, water supply, diseases, and pests). A number of strategies can be employed that specifically enhance BNF through increased legume biomass. These include the use of legume genotypes adapted to the prevailing edaphic and environmental conditions, procedures to improve legume plant density, irrigation (if available), the amelioration of soil nutrient toxicities or deficiencies, and the control of weeds and pests.^[1,4,10] However, as the formation of an active symbiosis is dependent on the compatibility of both the diazotrophic microorganism and the legume host, local practices that limit the presence of effective rhizobia (no inoculation, poor inoculant quality) will also be crucial in determining the legume's capacity to fix N (Table 3), as will any management decisions that directly affect soil N

fertility (excessive tillage, extended fallows, fertilizer N, and rotations), since mineral N is a potent inhibitor of the N₂ fixation process.^[1,7,9,10]

CONCLUSION

Symbiotic associations between legumes and rhizobia are responsible for the greatest contributions of BNF in agricultural systems. Research trials suggest potential annual inputs of fixed N by most legumes equivalent to several hundreds of kilograms of N per hectare. However, data collected from pulses, legume oilseeds, and pastures growing in farmers' fields generally indicate the levels of BNF much lower than the potential values observed under experimental conditions. So while legumes should routinely be fixing >100 kg/ha each year, in reality, they usually do not. Strategies are available to improve BNF beyond what is being achieved. For example, provided that a legume crop is abundantly nodulated and effectively fixing N₂, enormous benefits in terms of crop production and N₂ fixed can be derived from the application of good agronomic principles (see *Biological Nitrogen Fixation*, p. 227–231). But the ability to overcome constraints at the farm level may be limited because either the relevant technologies are not in the hands of the farmers, or they cannot readily adopt them because of lack of knowledge and information, economic constraints, or operational imperatives. While the global inputs of fixed N by legumes may be considerably less than their genetic potential and is lower than the amounts of N applied as fertilizer each year, some 15 million tonnes of N are harvested annually from legume crops, and many million tonnes more will be consumed by animals in legume-based forage, and there are a number of environmental advantages in relying on BNF over fertilizer N to produce such large quantities of high-quality protein.^[11,12]

Biological Nitrogen Fixation: Enhancement Techniques

David Francis Herridge

Environmental and Rural Sciences, University of New England, Armidale,
New South Wales, Australia

Abstract

Legume biological nitrogen fixation (BNF), resulting from the symbiotic relationship between legumes and rhizobia, a soil bacteria, is a key process in agriculture with the crop legumes alone supplying about 24 million tons of nitrogen (N) annually for global grain production. The specific amount of N fixed by a legume crop in a farmer's field essentially depends on the productivity of the crop and the level of soil mineral N in the field. Productivity can be enhanced by optimizing crop use of growing season and space, and nutrient and water resources, with careful attention to species and cultivar choice, planting time, row spacing and plant density, pest, disease and weed control, and crop nutrition. The suppressive effects of soil mineral N on BNF can be reduced through practices that lead to reductions in soil mineral N, such as no-tillage. Inoculation of legumes at sowing is another practice that can enhance BNF. It is virtually impossible to obtain accurate figures, but it is likely that about 50 million hectares of crop legumes, equivalent to about 25% of the area sown globally, are inoculated each year.

INTRODUCTION

Legume biological nitrogen fixation (BNF) is a key process in agriculture with the crop legumes alone supplying about 24 million tons of nitrogen (N) annually for the world's grain production. Soybean is the most widely grown of the crop legumes with 111 million hectares harvested in 2013 and almost half the area in just two countries—Brazil and Argentina. Soybean makes a substantial contribution to global N fixation with an estimated 17.4 million tonnes fixed annually. Notwithstanding these impressive statistics, legume BNF, resulting from the symbiotic association between legumes and rhizobia, a soil bacteria, remains essentially unmanaged by farmers. In many parts of the world, the legumes are considered secondary crops and are not provided the inputs and management given to major crops, usually cereals. In other situations, economic factors mitigate against the use of appropriate inputs. This lack of management, coupled with environmental influences beyond the control of farmers, results in wide variations in BNF, commonly between nil and approximately 400 kg N/ha.

FACTORS AFFECTING BNF

The factors accounting for variations in BNF are quite simple. Provided that there are adequate numbers of highly effective rhizobia in the soil in which the legume is growing, BNF is essentially determined by the growth of the legume (i.e., the legume's N demand) and the proportion of legume N derived from BNF (%Nd_{fa}), as follows:

$$\text{Legume BNF (kg/ha)} = \frac{\text{Total N yield (kg/ha)}}{100} \times \% \text{Nd}_{\text{fa}}$$

Thus, legume BNF can be enhanced by increasing total N yield and/or increasing the %Nd_{fa}. With the majority of legumes, there is sufficient genetically based capacity for BNF to supply the entire amount of N that is required for plant growth.^[1,2] For example, the data of Evans et al.^[3] highlighted the very strong relationship between shoot dry matter and N₂ fixed for the temperate crop legumes, lupin (*Lupinus angustifolius*) and pea (*Pisum sativum*), and indicated sufficient BNF capacity of lupin to support shoot dry matters of up to 14 t/ha.

There are cases, however, where insufficient BNF capacity limits legume yield, the most notable being common or dry bean (*Phaseolus vulgaris*). Redden and Herridge,^[4] after reviewing the genetic capacity for BNF of >1000 genotypes of *P. vulgaris*, concluded that BNF could supply only a fraction (<30%) of the N demand with the remainder supplied by soil or fertilizers. Clearly, BNF of this species is weak, and management for yield will only have limited benefits for BNF.

LEGUME YIELD AND BNF

Just how much influence does legume yield have on BNF? The simple answer is a great deal. Researchers in Australia's northern grain belt^[5] reported that 96% of the variation in BNF of alfalfa (*Medicago sativa*) was related to the variation in legume aboveground biomass with 28 kg shoot N fixed for every ton of biomass produced. A study of BNF

of pulse (pea) and pasture species [alfalfa and annual medic (*Medicago truncatula*)] showed that 99% of the variation in BNF was associated with differences in biomass production (23 kg shoot N fixed/t biomass).

Similar close relationships between biomass and BNF were reported by Evans et al.^[3] in a network of 21 experiments at 10 locations of the cool-season pulses, lupin and pea, in southeastern Australia. They reported variations in BNF of 36–400 kg N/ha and 22–250 kg N/ha for the two species. The original data were presented as fixed N in shoots only; whole-plant BNF was calculated by multiplying shoot N by 1.4 to account for N in below-ground parts.^[6] Values for %Ndfa varied from 29% to 97% for lupin and 20% to 95% for pea. Almost 70% of the variation in BNF was associated with variation in legume biomass yield; an additional 20 kg shoot N/ha was fixed for every extra ton of biomass produced. Relationships between legume biomass production and BNF were summarized by Unkovich et al.^[6] as 17 kg shoot N fixed/t biomass for crop and pasture legumes combined, 21 kg shoot N fixed/t biomass for crop legumes alone, and 16 kg shoot N fixed/t biomass for pasture legumes alone.

Soil Water

In the rainfed environments where the majority of agricultural legumes are grown, the overriding influence on plant growth (biomass yield) is the availability of water, which is either stored in the soil during the precrop fallow or falling as rain during growth. With the lupin and pea study referred to previously, 83% of variation in lupin biomass could be explained by in-crop rainfall.^[3] In an ancillary study, additional inputs of 75 and 125 mm water in the form of supplementary irrigation resulted in the enhancement of BNF at rates of 0.4–0.8 kg N/mm water. With the extra 125 mm water, BNF increased from 60 to 210 kg N/ha for lupin and from 47 to 150 kg N/ha for pea. The water use efficiency values for lupin and pea BNF were similar to published values of 0.3–0.5 kg N/mm for chickpea (*Cicer arietinum*).

These data highlight the close relationship between water availability, biomass production, and BNF. Irrigation is not often an option for farmers in dryland agriculture, and they have no control over seasonal weather. What they have some control over is the efficiency with which water is infiltrated into and stored in the soil, coupled with the efficiency with which the water is used by the legume.

Rhizobial Inoculation

Legume inoculation with rhizobia is a long established and successful practice, especially in countries in which legumes are widely grown, such as the United States, Australia, Canada, Brazil, Argentina, and India. It is virtually impossible to obtain accurate figures, but it is likely that about 50 million hectares of crop legumes, equivalent to about 25% of the area sown globally, are inoculated each year.

Since 1970, many experiments in different parts of the world have examined the need to inoculate. Results from 214 experiments of 10 legume species conducted by the University of Hawaii's NifTAL project indicated inoculation-enhanced yields in 53% of cases through enhanced BNF.^[7] Soybean (*Glycine max*) responded to inoculation in 65% of experiments, which is not surprising because of its specific requirements for rhizobia. In the same study, analysis of 305 soil samples from 17 countries indicated that only 14% of soils contained rhizobia that were effective on the highly bred American soybean.

These figures highlight the uncertainty regarding the benefits of and need for inoculation. In countries where inoculants are readily available, inoculation is generally recommended as a practice for all legume sowings. Unfortunately, few farmers in less-developed countries have access to high-quality inoculants or use inoculants as a normal part of their legume cultivating practices. In these situations, potential yield is lost unless soil N uptake is supplemented with fertilizer N (with additional cost to the farmer), or the soil already contains adequate numbers of effective rhizobia.

Legume Agronomy

Strategies to enhance legume biomass and legume BNF include optimizing crop use of growing season and space, and nutrient and water resources with careful attention to species and cultivar choice, planting time, row spacing and plant density, pest, disease and weed control, and crop nutrition. In the following sections, experiments are discussed in which legume BNF was enhanced through management for biomass yield. The examples are specific for particular sites and seasons and are not meant to be prescriptive; rather, they serve to illustrate how management practices can be changed to enhance BNF.

Species/Cultivar Choice

Matching the species and cultivar of legume to the edaphic (soil) and environmental conditions can lead to enhanced BNF. In the same lupin and pea study referred to previously, BNF of lupin was approximately 80% greater than that of pea on the acidic soils because of substantially increased biomass yield and marginally improved %Ndfa (Table 1). The reverse was the case on the alkaline soils in the study; on those soils, pea outyielded lupin by approximately 60% and fixed approximately 80% more N.

Planting Time

Optimizing planting time to take full advantage of rainfall and temperatures in the growing season and to minimize deleterious effects of pest and disease cycles can provide options for enhancing BNF. In the Australian pea experiment (Table 1), BNF was increased from 64 to 180 kg N/ha

Table 1 Examples of enhancement of legume BNF through practices to increase legume yield.

^aIn most cases, values shown are the means of several sites and/or seasons.

^bOriginal values for shoot N recalculated as crop N using multiplication factors of 2.0 for chickpea, alfalfa, and subterranean clover, and 1.4 for pea, lupin, and lentil.^[6]

by planting 54 days earlier. Most of the increase was because of the larger biomass crops.^[8]

In a more radical departure from traditional agronomic practice, Beck et al.^[9] in Syria increased BNF of chickpea, from 7 to 143 kg N/ha, by planting in winter rather than in spring. This was made possible by the introduction of cold-tolerant, ascochyta blight [*Ascochyta rabei* (Pass.) Labrousse] resistant varieties. The longer growing season

allowed the crop to utilize rainfall more efficiently and produce greater biomass, which resulted in the enhanced BNF.

Plant Density and Row Spacing

Within the limits of site and environment, narrow row spacing and/or high plant density can result in enhanced BNF. In on-farm surveys of 51 chickpea and faba bean (*Vicia faba*) crops in Australia's northern grain belt, Schwenke et al.^[12] reported that crop biomass was greatest in narrow rows and that %Ndfa was positively correlated with plant density. In pasture systems in southeastern Australia,^[10] increasing alfalfa numbers from 5 to 40 plants/m² resulted in producing more than double the amount of crop biomass (from 246 to 548 kg N/ha) and BNF (from 128 to 300 kg N/ha; Table 1).

Pest Control

Pests and diseases will reduce legume biomass. For example, a major constraint to lentil (*Lens culinaris*) production is the *Sitona* weevil, the larvae of which feed on the N₂-fixing root nodules. Destruction of nodules can be as high as 80%. Application of carbofuran (2,3-dihydro-2,2-dimethyl-7-benzofuranol methylcarbamate) during sowing controls the pest. In the Syrian study reported by Beck et al.,^[9] use of the insecticide resulted in a 20% increase in both biomass and BNF (Table 1).

Weeds compete with the legumes for light, water, and nutrients, and their control benefits the production of legume biomass. Herbicide spraying of grassy weeds in subterranean clover (*Trifolium subterraneum*) pastures in southeastern Australia resulted in a 27% increase in biomass and a 23% enhancement of BNF (Table 1). Similar results were reported^[13] for a mixed annual medic–alfalfa pasture in which winter cleaning of grassy weeds increased BNF by 110 kg N/ha.

Other Soil Constraints and Plant Nutrients

Other soil constraints include acidity, salinity, nutrient toxicities, and nutrient deficiencies. Such constraints must be addressed if potential legume biomass production is to be realized. Research has also established that the N₂-fixing legumes may have additional edaphic and nutritional requirements, compared with the non-N₂-fixing plants.^[14] Examples are the higher requirement by N₂-fixing legumes for calcium, boron, iron, and molybdenum.

Soil acidity and phosphorus (P) deficiency are common constraints to legume BNF. In a 3-year study at three sites in southeastern Australia, N yields and BNF of subterranean clover-dominated pastures were increased from 65% to 70% with P fertilizer and from 120% to 130% with a combination of lime and P (Table 1). Lime increased pH and reduced extractable aluminum and manganese, both of which are toxic to legumes and rhizobia at elevated

concentrations. In an ancillary study, also involving subterranean clover at three sites, crop biomass N and BNF were increased by 80 and 70 kg N/ha, respectively, with fertilizer P.

%NDFA AND BNF

At any level of yield, increasing %Nd_{fa} results from practices to reduce soil nitrate suppression of BNF. This can be achieved in a number of ways, most dramatically by land use, and, to a lesser extent, by tillage practice and stubble and mulch management.

Land Use and Crop Sequence

Rainfed chickpea grown immediately after sorghum (*Sorghum bicolor*) fixed 183 kg N/ha, compared with 54 kg N/ha by chickpea in previously fallowed soil (Table 2). The Nd_{fa} values were 84% and 19%, respectively. The differences in BNF were because of the large differences in soil nitrate levels at sowing—17 and 226 kg N/ha—affecting the %Nd_{fa} values.

Soybean BNF was similarly enhanced when grown on land that had previously grown unnodulated soybean, rather than on land used for nodulated soybean cultivation or on fallowed land (Table 2). Effects on BNF were again mediated through soil nitrate levels affecting plant nodulation and %Nd_{fa}. Unnodulated soybean reduced soil nitrate levels more than nodulated soybean because the residues of the former were N deficient and would have immobilized some of the mineral N, as it was released from organic matter. Many other studies relating BNF to crop sequence and land use report similar findings, including on-farm surveys of 33 soybean crops^[18] and 51 chickpea and faba bean crops^[12] in Australia’s eastern grain belt.

Tillage

Cultivation accelerates the mineralization of organic N to plant-available mineral N in soils, with the result that cultivated soils often have an additional 20–25 kg nitrate–N/ha in the root zone, compared with untilled (or no-tilled) soils. For cereals under no-tillage, additional fertilizer N may be required to supplement the reduced soil nitrate N. For legumes, however, the lower nitrate N should result in enhanced BNF. In a series of experiments comparing effects of tillage practice on soybean production, the no-tilled soybean produced more nodules and more biomass, had higher %Nd_{fa}, and fixed more N (320 vs. 246 kg/ha) than the cultivated crops (Table 2).

Although soil nitrate levels were not measured in this experiment, it is highly likely that reduced soil nitrate resulted in the higher %Nd_{fa} value for the untilled soybean. It was interesting that the untilled crops produced 8% more biomass N than the cultivated crops. Untilled soils are often wetter than cultivated soils, which may be crucial in arid to semiarid, rainfed environments. An additional 40 mm plant-available water could mean an extra 25 kg biomass N/ha. Thus, although the extra 74 kg N fixed/ha should be mainly attributed to the reduced nitrate suppression (and enhanced %Nd_{fa}), the wetter untilled soils may have contributed to increased growth.

CONCLUSION

The previous examples show clearly that management options for enhancing BNF are available to farmers. The options roughly fall into two categories—those that increase biomass yield and those that reduce soil nitrate. As stated earlier, the examples are site and species specific and are not meant to be prescriptive. The means by which

Table 2 Examples of enhancement of legume BNF through practices to increase %Nd_{fa}.

Biological Nitrogen Fixation: Forms and Regulating Factors

Abstract

Nitrogen (N_2) fixation is the basis of the global N cycle. Therefore, it is not surprising that the ability to fix atmospheric N_2 evolved in the “primeval soup” and is deeply rooted in the evolutionary tree of life. Despite this, nitrogenase remains an enzyme exclusive to prokaryotes; no eukaryote has been described that can fix N_2 except through a symbiotic relationship.

VARIOUS TYPES OF BIOLOGICAL NITROGEN FIXATION

Members of both the Archaea and Eubacteria can fix nitrogen (N_2), and, even within the Eubacteria, nitrogenase is widely distributed among the various bacterial divisions.^[1] The most widely distributed form of nitrogenase is known as the molybdenum nitrogenase, which, as its name suggests, contains molybdenum. Other nitrogenases in which molybdenum is substituted by iron or vanadium have been found in free-living bacteria such as *Azotobacter*. The structure and the synthesis of nitrogenases are reviewed in detail by Smith.^[2] A novel mechanism for N_2 fixation was described by Ribbe, Gadkari, and Meyer^[3] in *Streptomyces thermoautotrophicus*. This nitrogenase is very unusual: it apparently uses superoxide as its reductant and contains a molybdopterin cofactor as the active site.

The diversity of types of N_2 fixation arises from the multiple modes by which bacteria and eukaryotes have coevolved to meet the rather exacting demands of active N_2 fixation. Associations range from loose relationships of free-living heterotrophic bacteria with plant roots to highly evolved symbioses that involve complex morphological differentiation of both partners (Table 1). Symbioses between N_2 -fixing bacteria and eukaryotes range from the *Cyanobacteria* (often referred to as blue-green algae) with fungi in lichens, Cycads, and *Gunnera*; actinomycetes (generally placed in the genus *Frankia*) with a range of angiosperms; and the rhizobia with legumes (and the single non-legume genus *Parasponia*). N_2 -fixing bacteria tend to occupy habitats abundant in carbon (C) but, despite many claims, these cannot be considered to be true symbioses. Examples are N_2 -fixing bacteria in plant rhizospheres (often referred to in the literature as

“associative symbioses”) and endophytic N_2 -fixing bacteria present in the vascular tissues of graminaceous plants such as sugarcane.^[5]

INTRODUCTION OF N_2 -FIXING ORGANISMS

Obviously, if N_2 -fixing organisms are not present within the ecosystem, they cannot contribute to the N cycle. In the case of agriculture, the identification of new niches for introduction of legumes into cropping systems is one of the most important means of increasing inputs from N_2 fixation.^[6] Another example of the introduction of N_2 -fixing organisms that is practiced on a commercial scale is inoculation with rhizobia; this industry has existed for almost 100 years. Legumes that warrant rhizobial inoculation are fairly specific in their symbiosis and often only require inoculation when they are transported to regions outside their centers of diversity or to where they are not traditionally grown.^[7]

ENVIRONMENTAL FACTORS THAT REGULATE N_2 FIXATION

As with all biological processes, environmental conditions such as temperature and moisture availability regulate the rates of N_2 fixation. There is a range of adaptation among N_2 -fixing bacteria and symbioses. As indicated previously, many methanogenic archaeobacteria can fix N_2 and some of these are found in hot springs. By contrast, lichens are the dominant, primary producers in cold tundra. The optimum conditions for N_2 fixation therefore differ strongly, obviating generalizations in description of ideal environments. Extreme temperatures, whether hot or cold, and extremes

of drought or water logging are important constraints to N₂ fixation in particular climates. The focus in this entry is placed on environmental variables that commonly act as limiting factors for N₂ fixation at different scales.

Regulation at the Physiological Scale

The triple dinitrogen bond is highly stable and large amounts of energy are required for N₂ fixation in the form of adenosine triphosphate and electrons. Aerobic respiration is necessary to provide sufficient energy for high rates of N₂ fixation, yet the nitrogenase enzyme is denatured irreversibly on exposure to molecular oxygen. This is what has been termed as the “oxygen paradox” of N₂ fixation and a host of mechanisms has evolved to circumvent this

problem (Table 1).^[8] In legume/rhizobium symbioses, it is believed that the response of N₂ fixation to the majority of environmental stresses is regulated by altering the supply of oxygen to the N₂-fixing “bacteroids.” This is mediated by the presence of an “oxygen-diffusion barrier” that has a variable permeability to oxygen.^[9]

A common feature is the repression of nitrogenase activity by the presence of available N in combined mineral forms (NH₄⁺ and NO₃⁻). In cultures, active N₂ fixation by free-living bacteria is only strongly induced when the mineral N becomes limiting for bacterial growth. In N₂-fixing symbioses, availability of large amounts of mineral N can act to repress N₂ fixation in several ways. Nodule formation and development are inhibited by combined N (in what is sometimes referred to as “autoregulation”), or the activity of N₂-fixing nodules can be suppressed (in what is termed N feedback regulation).^[10] This can be viewed as an evolutionary demand of the symbiosis, as it demonstrates that the extent of development of colonization of plant tissues is under the firm control of the host, effectively preventing parasitism.

Nutrient Limitations

A range of nutrients are required for N₂ fixation.^[6,10] Among the potential nutritional constraints to N₂ fixation, availability of phosphorus (P) is often overriding in both agricultural and natural systems. This is true even in aquatic systems where P limits the growth and N₂ fixation of Cyanobacteria and *Azolla*.^[11] Deficiency of P forms part of the “soil acidity complex” that limits N₂ fixation in acid soils, particularly in old, weathered soils of the tropics^[12] or in volcanic soils.^[13] These are precisely the conditions that favor deficiency of molybdenum, which is an essential component of the nitrogenase enzyme. Molybdenum deficiency is relatively uncommon except in older, weathered tropical soils but can be locally important. Many other major- and micronutrients have special roles in N₂ fixation; for instance, calcium is important for infection and nodule formation in legumes and cobalt is required by N₂-fixing bacteria for electron transport.^[6,10]

Toxicities

As with deficiencies, toxic effects can be manifested on both N₂-fixing bacteria and their symbionts. Toxicity of aluminum is of particular note: It appears to interfere specifically with the process of infection and nodule formation in legumes and is a major problem for survival of N₂-fixing bacteria in acid soils.^[6] Heavy metals appear to be particularly toxic to N₂-fixing bacteria in soil. This is true for free-living heterotrophic N₂-fixing bacteria, *Cyanobacteria*, and rhizobia that are all more sensitive to heavy metal toxicity than are host legumes.^[14]

Fig. 1 Changes in the relative importance of N_2 fixation at different stages in vegetation succession.

Source: From Gorham, Vitousek, et al.^[16] ©1979.

Regulation of N_2 Fixation at the Ecosystem Scale

The feedback of abundant combined N on regulating rates of N_2 fixation by both free-living bacteria and N_2 -fixing symbioses also acts to regulate rates of N_2 fixation at the scale of the (agro)ecosystem.^[15] In natural ecosystems, N_2 fixation is more important in early successional phases (unless other nutrients are strongly limiting; Fig. 1) but becomes relatively unimportant as the amount of N in the soil gradually accumulates.^[16] A resurgence of the importance of N_2 fixation at later stages of primary or secondary succession is supported when the system becomes more abundant in C and limited in N. Agricultural systems are also influenced in the same way: Rates of N_2 fixation are largest when N is limiting but other nutrients plentiful. In systems dominated by legumes, such as fodder banks, rates of N_2 fixation decline as the system accumulates N in the soil. Given that most agricultural production systems have high rates of N removal in harvested products, and hence slow rates of N accumulation, a large demand for high rates of N_2 fixation is the normal situation.

Biota

Lev O. Karpachevsky

Moscow State University, Moscow, Russia

Mikhail Karpachevsky

Faculty of Soil Science, Moscow State University, Moscow, Russia

Abstract

Biota—the totality of living organisms—is an important factor of soil formation, which creates organic matter, loosens rock, and modifies its composition by transforming into soil. In the absence of organisms, rocks are transformed into loose sedimentary materials similar to lunar regolith. Autotrophs, plants (their biomass on the earth is 2.4×10^{12} ton), as well as sulfur bacteria, iron bacteria, etc. build up organic matter. Heterotrophs, animals, and microorganisms (0.02×10^{12} ton) consume organic matter and decompose it to carbon dioxide and water. According to the type of feeding, they are divided into phytophages (feed on living plants), zoophages (predators), necrophages (eat animal corpses), and saprophages (consume decaying plants). The biota plays an essential role in creating the anisotropy of soils.

ROLE OF PLANTS

The biota is responsible for the redistribution of nutrients within the pedosphere, soils, and their accumulation in the upper layer of soil. This is especially true for such nutrients as carbon (C), nitrogen (N), phosphorus (P), and sulfur (S). Practically, all biological cycles are primarily driven by plants. Plants uptake chemical elements from soil, water, and atmosphere and buildup phytomass—the source of soil humus. The phytomass deposits on or in soil. The annual fall of plant litter, mortmass, on the soil surface ranges from 1 ton/ha to 30 ton/ha. Reserves of roots in soil may reach 20 ton/ha in tropical forest and 8–12 ton/ha in grasslands, temperate deciduous forests, and southern taiga. Up to 30% roots die annually. Roots of herbaceous plants and partly fine tree roots promote humus formation in the soddy horizon, undershrub and root horizon, and, partly, humic A horizon. These horizons are the soil factory of humus and it can form only in them.

The roots make up only 0.1–1% of soil by weight, while they directly affect soil in the vicinity up to 3 mm from the root surface, within the rhizosphere—the zone close to fine sucking roots. However, this generally has very little effect on the soil properties. Typically, the rhizosphere is densely populated with microorganisms, protozoans, and other invertebrates associated with these organisms.

If soil is continuously frozen, phytomass decomposition at the stage of the formation of litter (mortmass) slows down. The reserves of phytomass reach their maximum in forests—tropical, subtropical, temperate, deciduous, and southern taiga. The reserves of mortmass—fresh and partly decomposed litter—generally decrease from tundra and

northern taiga to steppes, accompanied by increasing humus content in soil (soil “mortmass”).

The biogeochemical importance of plants is also due to the fact that they uptake nutrients. The comparison of coefficients of enrichment (biological uptake) of plants relative to lithosphere and soil shows that plants add in the trophic chain additional amounts of sodium (Na), magnesium (Mg), potassium (K), calcium (Ca), copper (Cu), boron (B), P, S, bromine (Br), caesium (Cs), and gold (Au). Plants, when compared with soils, contain noticeably less amounts of fluorine (F), arsenic (As), and cadmium. At the same time, soil, when compared to lithosphere and sedimentary rocks, concentrates beryllium, S, chromine, zinc (Zn), As, molybdenum (Mo), silver (Ag), antimony, tin, iodine (I), Cs, Au, and Br. Soils on calcareous material contain much less Ca and barium. Plants, when compared to soil, accumulate more Na, Mg, K, Ca, manganese, cobalt, Cu, Zn, rubidium, Mo, Ag, and I. This accumulation is significant for B, P, S, Br, Cs, and especially Au. The enrichment of a geological layer with these elements and impoverishing in F, Na, Mg, chlorine, K, Ca, Cu, Rubidium (Rb), mercury, lead (Pb), and uranium (U) attests that this rock experienced a phase of soil formation.

Besides changing the chemical composition of rocks and accumulating humus, plants together with animals create the anisotropy of soils—a regular change in the system of soil horizons downward and spatial variation in properties of upper horizons (the soil pattern). Each particular plant and their group exert a specific effect on soil. Long-living immobile organisms, like trees, modify the soil during the whole life. However, their effect is not the same at various distances from the edifying plants, like large trees. Typically, soil pH in boreal ecosystems is lower near tree

Fig. 1 The correlation between humus content and soil acidity in eluvial horizons of sandy aluminum–iron podzols in pyrogenic pine forests of Surgut Woodland, Western Siberia. Samples from pink-colored eluvial horizons—the material from deeper horizons exposed by tree windthrow after wildfire and being actively bleached. Samples from sugar-white eluvial horizons—long bleached material of upper horizons.

trunks, while litter reserves and humus content are higher than under the canopy. The death of an individual tree or its group also has an important effect on soil formation. Thus, windthrow of trees mixes the soil, creating specific pit and mound topography. The traces of uprooting in soil can be recognized for decades. Fig. 1 shows the differences between two types of eluvial horizons of podzols found in pine forest, Western Siberia. Pink-colored eluvial horizons are the richer material from deeper horizons exposed by tree uprooting after wildfire and being actively bleached. Sugar-white eluvial horizons are long bleached material of upper horizons.

Local disturbances, like the death of a tree, may maintain the stability of ecosystem, while dynamically changing its internal structure through gap mosaic. Extended disturbances, like wildfires, create an opportunity for new species to colonize the landscape. Such plant communities in the course of their development (succession) alter an environment, making it more suitable to newer species. Long-term changes in soil properties following wildfire can be traced for hundreds of years as shown by Fig. 2. Thus, plants change soil properties (Table 1), structure soil, and increase its porosity relative to a parent material. Different plants and plant communities transform soil material in different way.

ROLE OF ANIMALS

The distribution of animal weight is similar to plants. Animals living on the ground comprise less than 0.5% of the weight of all animals in ecosystem. In turn, animals dwelling in litter and organic horizons (mortmass) make up about 90% of all animals by weight in tundra and northern taiga ecosystems. In steppe ecosystems, the weight of animals dwelling in mortmass decreases to 2–5% of the total

Fig. 2 Change in pH of drained and poorly drained aluminum–iron podzols in Surgut Woodland, Western Siberia, in the course of successions after wildfire.

zoomass as litter reserves decrease, while up to 90–98% of the zoomass occurs in the soil. Most animals in grasslands and deserts live in soil, while in taiga they occur in forest litter. The distribution of microbial mass coincides with that of zoomass—in taiga its maximum occurs in litter, while further south it shifts to soil.

Major components of soil fauna are protozoans (amoeba, infusoria, etc.), worms, beetle larvae, arachnoids, slugs, etc. Saprophages play a prominent role in soil formation, especially burrowing animals—moles, ground squirrels, marmots, and mice. Soil-dwelling animals are subdivided into groups: geobionts (constantly live in soil), geophiles (spend a major part of their life cycle in soil), and geoxenes (occasionally dwell in soil or use it as a shelter).

Earthworms (*Oligochaeta* and a group of the families Megadrili) are represented by the families Lumbricidae, Criodrilidae, Ocnerodrilidae, Moniligastridae, Megascolecidae, etc. Most widespread are species of the family Lumbricidae. Earthworms are saprophages, part of them live in litter, others in soil. Litter-dwelling species, e.g., *Dendrobaena attemsi*, *Dechloromonas hortensis*, *Dendrodrilus rubidus*, *Allobophora parva*, *Eisenia submontana*, also live in decaying trees, dispersing organic material and partially mixing it with mineral soil. Earthworms dwelling in soil (species *Nicodrilus caliginosus*, *Allobophora chlorotica*, *Acaabaria biserialis*, *Allolobophora sturanyi*, *Kritidrilus calarensis*, etc.) pass soil through their gastrointestinal tract feeding on soil organic matter. Various ecological groups of the family Lumbricidae dwell on the ground; in soil and litter; in humus horizon; some large species make deep burrows and tunnels in soil. Earthworms produce coprolites—excrements rich in organic compounds, microorganisms, and N compounds; they often have high physical resistance. The upper layer of chernozems of old gullies and gray forest soils (Dnepropetrovsk Oblast, Ukraine) are 60–80% made up by earthworm coprolites. Groups of earthworms living in soil and litter and on the ground can penetrate far north; burrowing earthworms dwell even in dry forests of Mediterranean type. According to the type of feeding, earthworms are further subdivided into two ecological groups: feeding on leaf litter and detritus on the ground and proper soil forms feeding on

Table 1 Properties of soils (0–30 cm) in forest, virgin grassland, and arable land (according to N.S. Oreshkina).

Land type	Soil solids density (g/cm ³)	Porosity (vol %)	Specific surface (m ² /g)	Infiltration (mm/min)	Humus (% of mass)

raw humus. The number of earthworms in soils varies from one to hundreds earthworms per square meter. Earthworms feeding on litter on average consume up to 5 mg/g living mass per day. Earthworms may accelerate litter decomposition by 2 to 3 times. In the presence of earthworms (*N. caliginosus*, 20 worms and *Lumbricus terrestris*, 3 worms), the raw humus layer (H, or Oh) and humus layer, A, up to 5 cm thick develop. When earthworms are absent, only the F (Of) layer forms.

Other representatives of soil fauna are beetle larvae, ticks, annelids, collembolids, etc. basically dwelling in litter and the A horizon. Worms of the class Enchitridae, which ingest organic matter, are up to 10–25 mm long. In acid peat soils, there can be from 85,000 to 200,000 worms per square meter of soil, with a total weight of 0.3–30 g. Nematodes are small (up to 1 mm) segmented worms, whose number may reach several million individuals per square meter, feeding on decaying remnants of animals and plants, soil microflora, alga, and fungal mycelium. Sloths, with a size of 0.2–0.3 mm, dwell in mosses, feeding on small animals and plant cells. Myriapods, e.g., small symphylids, eat decaying plants and few are predators. Diplopoda, including millepedes, *Rossius kessleri*, eating dead plants can be up to 10–17 cm long in the tropics. Their exoskeletons accumulate Ca, strontium, U, Pb, etc. Few species are predators. Almost 95% of insects are dependent on soil during their life cycle. Some of them are phytophages—Elateridae, mole cricket, cutworm, phylloxera, May beetle larva, etc.—others are saprophages (larvae of Diptera—flies and mosquitoes: Bibionidae, Licoryidae, and Tipulidae). They decompose organic mass, transforming it into raw humus. Besides, beetle larvae (e.g., May beetle larvae) and beetles themselves live in soil.

Ants, which mix soil, are widespread in natural ecosystems (up to 50 kg/ha). They are partly predators and necrophages.

Wood louse, mainly saprophagous, is also common. Termites (5–22 g/m²) live in southern soils under conditions of deep groundwater. With the help of microorganisms dwelling in their alimentary tracts, they digest cellulose and burrow channels down to the depth of 8 m from the soil surface.

Animals 0.1–3 mm long are referred to as microfauna. The most abundant are ticks (up to 50,000 species and especially those with exoskeleton, beetle mites) feeding on fungus hyphae and decaying plant debris. Their number in forest litter reaches 200,000–300,000 per square meter with the weight of 20 kg/ha. They annually discharge (mg/m²): 1 in tundra, up to 6 in taiga, up to 8 in temperate deciduous forests, 2.2 in steppes, 1 in semi-deserts, 0.1 in deserts, and 13 in humid subtropics. Collembolids are lower wingless insects eating small plants (alga) dispersing plant debris. They give several generations per year with the total number of 1–50 million/m² and biomass of 0.2–6.4 g/m².

Protozoans are single-cell organisms inhabiting all soils, totaling up to 20 billion/m².

Rhizopoda, flagellates, and infusoria are 2–20 µm long and widely occur in soil. Their primary food is bacteria. Microorganisms are also considered part of the biota. They dwell on plant leaves, in soil, litter, and alimentary tract of all animals, participating in transformation of organic matter of ecosystems. Microorganisms also promote N fixation in soil (*Azotobacter*, *Clostridium pasterianum*, and *Rhizobium*), methane emission from soil, etc. In soils, they are adsorbed on mineral particles. Microorganisms participate in all processes of organic matter transformation at all trophic levels of the food chain. The number of microorganisms in soils is estimated in tens of thousands to billions of cells per gram of soil.

More than 1500 alga species occur in soil—more than 600 species of green alga, Chlorophyta, more than 400 species of cyanobacteria, Cyanophyta, nearly 300 species

of diatomic alga, Bacillariophyta, and nearly 200 species of yellow green alga, Xantophyta. The total biomass of soil alga is estimated to be 0.5–1 ton/ha. Alga fix N from the atmosphere and accumulate C, thus making the primary trophic level.

Fungi and actinomycetes play a considerable role in organic matter decomposition. The length of the mycelium of actinomycetes can reach 100–300 m/g of soil, increasing up to 6000 m/g in peatlands. The number of cells is estimated to be 2–300 million/g. Fungi decompose wood and litter and accelerate C cycling in ecosystems.

Animals contain a noticeably less variety of elements in their bodies and the total amount of elements [except C, O, N, and hydrogen (H)] are much less compared to plants. However, there is one part of animal activity, which is by scale comparable or even exceeds the biogeochemical activity of plants. This is the role of animals in reallocation and mixing of soil (burrows, disturbed grounds, passages in soil, etc.) and organic matter decomposition.

According to Abaturonov,^[1] mole discards may occupy up to 50% of plot area, totaling to 50 ton/ha. Typically, animals discard the material from deeper horizons on the soil surface—E, EB, and B in forests and AB, B, and BC in steppes and forest steppe. In taiga soils, discarded material is enriched with Ca and clay. In steppe soils, it is enriched with calcium carbonates, salts, and gypsum. The addition of elements to the upper layer of eluvial soils by animals often exceeds their input with plant litter. The discarded material becomes involved in soil formation. In the 0–7 cm layer, the humus content increases from 0.8% C during the first year after discard to 4% in 17 years. Animals like wild boar can actively reallocate soil matter—when abundant they may disturb 5–10% of the ground. Furthermore, they mix the upper and lower layers of soil down to the depth of 20 cm. Thus, in pine forests polluted during the Chernobyl accident, the radioactivity of soil decreased from 43 to 25 mR/h from 1987 to 1990, while in places disturbed by wild boar it decreased to 20 mR/h during the first year.

Dams made by beavers provoke soil waterlogging on midslopes and peat formation. Herbivores, including elephants trampling grasslands and savannas, make soil denser and decrease the content of humus in it. Excrements of mice in tundra and taiga lower the soil acidity permitting to survive pathogenic microorganisms infesting leptospirosis and pseudotuberculosis (*Hebdomadis*, *Grippytyphosa*, etc.).

Invertebrates and fungi are major destroyers of dead plant material. Fungi destroy wood and break down plant litter to trash. Observations show that trunks of beech, oak, and spruce with the diameter at breast height of 30–40 cm become fully decomposed on the soil surface in 100 years. Decomposing trunks, besides fungi and alga, are inhabited with mosses, higher plants, including woody species. In Northern European Russia, partly decomposed dead trunks are a place where seeds of spruce and fir may germinate, because large deadwood is not so quickly inhabited by

mosses and undershrubs (e.g., bilberry). In Kamchatka, saplings of larch also prefer deadwood, because trunks of decomposing trees are characterized by high moisture content and nutrient reserve, thus promoting young trees to grow on these substrata. Decomposing trunks are often inhabited with ants. Saprophages can be divided into those which feed only on organic substratum and whose excrements consist of 80–90% organic matter and organisms, which together with organic matter consume mineral substratum (many species of earthworms). The excrements of earthworms (coprolites) contain much more N and organic matter than the A horizon. Thus, the coprolites of *Eisenia nordeskioldi* contain 29% organic matter and 0.95% N, while those of *Dendrobena octaedra* contain 53% organic matter and 1.21% N. However, they contain more mineral matter than the excrements of wood louse (51–80% organic matter and 1.9% N), Bibionidae larvae (58–83% and 1.8%), and millipedes (76% and 1.5%). Fresh litter has about 90% organic matter and 1.5–1.9% N.

Although saprophages eating litter increase the ash content from 2–8% to 7–15%, they do not form soil humus. The humus matrix—humus tightly fixed on the surface of soil particles—is primarily formed by earthworms, which by three times accelerate decomposition of litter of various woody species. Soil worms mix organic matter with soil, thus promoting formation of the humus matrix in soil. Other animals and litter worms create raw humus, dispersed organic matter with higher ash content than fresh litter.

Biota and Disease-Suppressive Soils

Nicola Lorenz

Ohio State University, Columbus, Ohio, U.S.A.

Abstract

It has been estimated that globally 13% of crop yield is lost due to common plant diseases such as wilt, blight, and damping off triggered by soil-borne pathogens like *Fusarium* spp., *Phytophthora* spp., and *Pythium* spp. or *Rhizoctonia solani*. Plants affected by disease have been commonly treated with synthetic biocides, a method which is highly criticized in many countries. Thus, research has been focusing on soils showing resistance toward plant diseases to identify factors preventing plant disease outbreak. Soil disease suppression occurs when beneficial soil microorganisms such as *Pseudomonas* spp., *Gliocladium* spp., *Trichoderma* spp., *Bacillus* spp., and *Streptomyces* spp. are abundant and active in soils. Besides these known and well-described microorganisms, still unknown soil disease suppressive microorganisms are expected to be discovered in the near future using modern molecular techniques. Important biotic mechanisms for disease suppression triggered by soil organisms are: i) antibiosis, ii) competition for trace elements, nutrients and microsites, iii) predation or parasitism, and iv) hypovirulence. Advantageous for biological disease suppression are also soil organic carbon (SOC)-rich soils. Thus, studies have been focusing on amending soils with organic matter (OM) to enhance disease suppression. This entry highlights well-established and recent findings on biota and soil conditions supporting disease suppression.

INTRODUCTION

In conventional agriculture, the use of mineral fertilizers has generally replaced organic fertilizers, cover crops, and manure. Tillage depth and intensity have increased, which in return have led to decreasing soil organic carbon (SOC) stocks in agricultural soils.^[1] Concomitantly, the occurrence of soil-borne plant diseases increased triggering a rise in synthetic pesticide applications worldwide.^[2] In non-disease suppressive soil, soil-borne plant pathogens like *Fusarium* spp. and *Phytophthora* spp. are causing wilt and blight in vegetable crops. *Pythium* spp. are known to trigger damping-off, which is affecting seeds or seedlings. Another prominent fungal plant pathogen is *Rhizoctonia solani*, causing serious loss in potato (*Solanum tuberosum* L.) production worldwide. Higher organisms like soil-inhabiting nematodes, for example, *Meloidogyne* spp. and *Pratylenchus* spp. triggering root knot and root lesion as well as protozoa have the potential to substantially damage plants. Most plant pathogens are difficult to control, since they are increasingly resistant toward synthetic pesticides.

In response to this dilemma, studies have focused on alternatives to chemical pesticides, analyzing naturally disease suppressive soils by studying soil microbial biomass, diversity, and activity.^[3] Others have focused on SOC content or soil organic matter (OM) amendment and its role in supporting plant health thus restoring natural soil disease suppression.^[4] Numerous reviews and scientific studies

have been published on disease suppression in soils. This entry highlights some examples of disease suppressive biota in soils (*Pseudomonas* spp., *Gliocladium* spp., and *Trichoderma* spp.), followed by a discussion on the role of OM in disease suppression.

DISEASE SUPPRESSION IN SOILS

Disease suppressive soils are defined as soils in which certain diseases are suppressed due to the presence of microorganisms antagonistic to a pathogen.^[5] As outlined below, key soil microorganisms are involved in disease suppression; in addition, soil OM amendments have the potential to enhance soil disease suppression by promoting antagonistic microorganisms.

Soil Biota Suppressing Disease

Naturally disease suppressive soils are important subjects for research because the indigenous microflora is able to effectively protect plants from diseases. Soil disease suppression can be characterized as “general suppression,” where the entire microbial community is directly or indirectly involved in disease suppression. In other cases, certain members/taxa of the microbial community act as the main disease suppressors, this phenomenon is referred to as “specific disease suppression.” For example, specific disease suppressive microbial species or groups

such as *Pseudomonas fluorescens*, *Streptomyces* spp., *Agrobacterium radiobacter*, and fungi like *Gliocladium* spp. and *Trichoderma* spp. act to suppress *Pythium* spp. or *R. solani*.^[6] Those organisms use antagonistic mechanisms against plant pathogens. Mechanisms of plant protection differ from organism to organism, and relationships and mechanisms steered by environmental conditions are highly complex. A basic principle holds true when the antagonist controls the pest: It is a matter of tipping the balance toward disease suppression, which depends on the whole microbial community (general suppression), the type of pathogen and antagonist (specific suppression), the place and time of the pathogen's and antagonist's occurrence, their metabolic activity,^[7] as well as the soil condition (SOC content, pH, and nutrient contents^[8]).

Basic mechanisms of biological disease suppression are: 1) antibiosis (inhibition or destruction of the pathogen by a metabolic product of the antagonist, e.g., lytic enzymes); 2) competition for trace elements, nutrients, and microsites; 3) parasitism or predation; and 4) hypovirulence.

Antibiosis occurs when antagonists are metabolically active producing metabolites or enzymes harmful for the pathogen(s). As a result of competition for trace elements, disease suppression occurs, this happens when antagonists are more successful in using nutrients for their growth and thus effectively outcompeting pathogens. Predation typically refers to species that feed at higher trophic levels; however, it has also been used for the actions of microbes, for example, protists and mesofauna, such as fungal feeding nematodes and microarthropods, which consume pathogen biomass. Hypovirulence refers to the reduction of virulence of a pathogenic strain.^[7]

Pseudomonas spp.

The suppression of root diseases by *P. fluorescens* strain CHA0 was related to the production of the secondary metabolite 2,4-diacetylphloroglucinol (DAPG).^[9] Several studies have shed light on the regulation of DAPG, an antifungal compound being released by *Pseudomonas*. Both, pathway-specific and general regulators have been reported controlling the biosynthesis of DAPG. It was observed that DAPG production by *P. fluorescens* strain CHA0 can be affected by plant phenolics indicating that plant-derived compounds have the potential to regulate the activity of microorganisms involved in disease suppression. It was also observed that diverse *Pseudomonas* spp. populations correlated with increased antagonistic activity measured by the production DAPG and other antibiotics, which significantly decreased fungal pathogens. In addition, a review on the rhizosphere ecology of tobacco (*Nicotiana glutinosa* L.) revealed that suppressiveness to *Thielaviopsis basicola*-mediated black rot is largely attributed to DAPG-producing *Pseudomonas* spp.^[10] In a *R. solani*-suppressive

soil, *Pseudomonas* spp. and *Trichoderma* spp. have been identified as some of the most active microbial taxa engaged in disease suppression^[6]).

Gliocladium spp. and *Trichoderma* spp.

The soil-borne fungi *Gliocladium* spp. and *Trichoderma* spp. have been studied comprehensively for their suppressiveness of plant pathogens. Mainly three mechanisms of biotic disease suppression are used by these fungi to prevent disease outbreak, namely antibiosis, competition, and mycoparasitism. An example for mycoparasitism is *Gliocladium roseum*, which is known as a parasite for fungi and nematodes. In addition, *G. roseum* produces a wide range of volatile organic compounds that are toxic to organisms including other fungi, bacteria, and insects and is of interest as a biological pest control agent.^[11]

Several strains of *Trichoderma* have been developed as biocontrol agents against fungal diseases of plants,^[6] since they have been shown to effectively suppress soil-borne fungal plant diseases. The various mechanisms include antibiosis, parasitism, inducing host-plant resistance, and competition. *Trichoderma* spp. produce enzymes (chitinases, glucanases, cellulases, and proteases) that are highly effective in suppressing *Pythium* spp. or *R. solani* in soils.^[8] Most biocontrol agents are derived from the species *Trichoderma harzianum*, *Trichoderma viride*, and *Trichoderma hamatum*. The biocontrol agent generally grows in its natural habitat on the root surface and thus specifically affects root disease but can also be effective against foliar diseases.

Research has highlighted the importance of previously unknown fungi for disease suppression, which revealed that disease suppressive soils were hosting mycoparasites such as *Xylaria* spp. with known antibiotic activity against plant pathogenic fungi. Biota plays a significant role in disease suppression, but more research is needed to fully understand the mechanisms and specific microorganisms controlling diseases. Because soils are complex ecosystems, the factors controlling disease are therefore highly diverse and not only restricted to biotic interactions but also steered by soil properties.^[12]

Soil OM Amendments and Disease Suppression

Compost application to soils has been shown to be a successful OM amendment to prevent plant disease outbreak. Analyzing 18 different composts, Termorshuizen et al.^[13] revealed that compost has generally a positive effect or no effect on disease suppression and very rarely stimulated disease. Another study has shown that complex organic amendments (a mixture of compost, slurry, and dung) have resulted in greater *Fusarium* wilt suppression compared to adding them separately. In a review, Metha

et al.^[14] highlighted that compost application to soils is a promising tool to prevent plant disease outbreak. However, since microbial communities in compost are the main drivers of disease suppression, it is a matter of promoting antagonistic microorganisms in compost to affectively control pests. Studies enriching compost with beneficial microorganisms such as *Trichoderma* spp. have been conducted and shown increased disease suppressiveness. But there are expectations for beneficial but unknown microorganisms (especially non-cultivable microorganisms) to be discovered in compost by modern molecular approaches. A better understanding of compost-inhabiting microorganisms will increase the use of compost in enhancing soil disease suppression.

Different complementary mechanisms have been proposed to explain the suppressive capacity of OM amendments like compost. For example, these include enhanced activities of antagonistic microbes, increased competition against pathogens for resources hampering fungal growth, or induction of resistance in the host plants.^[15]

However, despite the potential benefits of organic soil amendments, there are several concerns about its use, since several studies have indicated that the effects of compost on disease suppression are variable. In several cases, compost and other organic amendments either enhance disease severity or show no effect.^[13] Negative effects of OM amendment were often associated with increased inoculum and growth of pathogenic fungi and oomycetes. In addition, it was discussed that the release of phytotoxic compounds could damage plant roots and predisposes them to pathogen attack. The inconsistent disease control results obtained with compost amendments, with both disease suppressive and conducive (disease increasing) effects, show that more research is needed to fully understand disease suppressive mechanisms of composts.^[13]

Besides compost, biochar has been discussed for its potential to decrease disease outbreak. While being mixed with compost and being amended to soils, it was shown that mixed biochar amendments affected soil mycorrhizal associations and thus prevented *Fusarium* rot in asparagus (*Asparagus officinalis* L.) suggesting that biochar has the potential to stimulate antagonistic microbial communities preventing disease outbreak.^[16] The reduction of application of synthetic pesticides by biochar application on soils appears plausible but more research is needed to fully understand the effect of biochar on disease suppression.^[17]

CONCLUSION

Disease suppressive soils have been shown to suppress common diseases such as wilt, blight, and damping off triggered by *Fusarium* spp., *Phytophthora* spp., and *Pythium* spp. It has been shown that disease suppressive

soils host key soil microorganisms involved in plant disease suppression such as *Trichoderma* spp., *Gliocladium* spp., *Pseudomonas* spp., *Bacillus* spp., and *Streptomyces* spp. Besides these known and well-described microorganisms, more, unknown soil dwelling microorganisms are expected to be involved in disease suppression. Disease suppressive microorganisms use several mechanisms, namely antibiosis, competition, parasitism/predation, and hypovirulence, which hamper disease outbreak. Overall, successful disease suppression in soils is highly dependent on the type of pathogen and antagonist (specific suppression), the place and time of the pathogen's and antagonist's occurrence, their metabolic activity, and the soil condition (SOC content, pH, and nutrient contents). In general, SOC-rich soils offer the most favorable conditions for disease suppression.

Compost has been shown to promote disease suppressive soil; however, the effects of compost are not always beneficial. It has been revealed that compost can promote plant pathogens and can trigger the release of phytotoxic compounds damaging the plant root, thus predisposing plants to disease. More research is needed to fully understand the highly complex disease suppressive mechanisms in soils.

Biotechnology

Manas R. Banerjee

Laila Yesmin

Research and Development Division, Brett-Young Seeds Limited, Winnipeg, Manitoba, Canada

Abstract

Although there are several genetically modified products commercially available, biotechnology has no magic solution to all our problems. It has tremendous promise, but to attain its full potential it must be environmentally compatible, economically viable, and socially responsible. This is an ever-emerging technology that needs proficient management of its development. However, biotechnology may be the single most sought-after tool at our disposal capable of making significant contribution toward the food security and sustainable development.

INTRODUCTION

Biotechnology is an applied field that can be viewed from many perspectives. To some, it is the age-old technique of selecting better cultivars and wine production, and to others, it is the recombinant DNA technique that creates the basis of modern biotechnology. The term “biotechnology” may suggest a single subject, but in reality it is a multidisciplinary approach to utilize science for the benefit of our society. The word “biotechnology” originates from Greek words “bios” and “technologos,” which means living and technical study, respectively. The literal meaning of biotechnology is, thus, the technical study of living things. The simplest way to look at biotechnology is the use of living organisms to produce goods and services for industrial purposes. *Chambers Science and Technology Dictionary* defines biotechnology as “the use of organisms or their components in industrial or commercial process, which can be aided by the techniques of genetic manipulation in developing, e.g., novel plants for agriculture or industry.”^[1] Furthermore, the *Macmillan Dictionary of Biotechnology* defines the term as “the application of organisms, biological systems, or biological processes to manufacturing and service industries.”^[2] This definition actually includes any process in which organisms, tissues, cells, organelles, or isolated enzymes are used to convert biological or other raw materials to products of greater value, as well as the design and use of reactors, fermenters, downstream processing, and analytical and control equipment associated with biological manufacturing processes.^[2] Biotechnology has been used for centuries in fermentation, cheese, and bread making, but it involves innovative devices like molecular techniques, *in vitro* techniques, genetic engineering,

cloning, protein manipulation, monoclonal antibodies, and stem cells. Biotechnology is no longer the applied branch of biological sciences rather it is a strategic technology having diverse application on the socioeconomic development and sustainability of the industrialized countries (Fig. 1).

APPLICATIONS AND PROSPECTS

Biotechnology has made remarkable progress over the last decades and is well integrated with technical improvement of processing and instrumentations. For example, penicillin manufacturing has changed over the years with the development of efficient strain and improved operational techniques. The same is true for many pharmaceutical products, drugs, fine chemicals, biopolymers, energy, and processed food products. In developed world, major biotech industries are in pharmaceutical, food, agriculture, environment, and health sectors, whereas in developing countries, food and agriculture biotechnology are progressing rapidly.

With the introduction of genetic engineering in the agricultural sector, biotechnology has made fabulous advances in crop yield and quality. Agronomic traits have been successfully developed or being developed through genetic manipulation of crop plant. For instance, “roundup-ready” soybean and canola were developed to protect from herbicide and “Bt” cotton and corn to provide protection against insect damage. Genetically modified (GM) crops are commercially grown in more than 40 countries, with over 110 million ha under cultivation.^[3]

This technology reached almost one billion acres of farmland in 2005, and millions of farmers are using it. Crops like soybean, oilseed rape, corn, and cotton have

Fig. 1 The contribution of science toward the application of biotechnology.

the largest acreages and are primarily grown in countries like the United States, Canada, Argentina, and China. Biotechnological applications in agriculture have a potential market estimated at \$67 billion per year.^[4] Many developing countries are embracing agriculture biotechnology with the hope to increase their food production to meet the demand of growing population, as food security is their main concern. Food and Agriculture Organization of United Nations recognizes the potential of increasing production in agriculture, fisheries, and forestry through GM technology. This might not completely eradicate world food shortage, but it could definitely contribute to the food security particularly in the developing world. With increasing yield, GM technologies have also been shown to reduce pesticide use and increase farm profitability. The technology has been extended to local crops like banana, cassava, plantain, rice, and sorghum for abiotic stress tolerance and quality. “Golden rice” capable of producing provitamin A (beta-carotene) and iron-rich rice is also the example of this novel technology. As such, more challenging works in the areas of stress resistance, crop yield, and quality enhancement are on the horizon. Some microbiologically derived biopesticides and biofertilizers are already in the marketplace making strides in boosting agricultural production. Besides, biotechnology indirectly aids in carbon sequestration by reducing tillage that minimizes soil erosion, helps water retention, and reduces carbon escape from soil. Introducing mycorrhizal fungi to increase plant growth that enhance moisture and nutrient uptake resulting in plant capacity to sequester more carbon is another example. Biotechnology is also contributing to the improvement of biodiversity and restoring ecological health via the reduction of carcinogenic chemical use. Advances on effective identification

of genes and genomic and proteomic research play a tremendous role in improving biodiversity as well. The preservation of terrestrial ecosystem is an important step to maintain biodiversity as ecological damage by deforestation already wiped out and/or threaten the existence of many valuable species. If GM technology could produce more food per unit of existing farmland, then more land will be protected for wildlife and forest species. Biotech research based on gene called “cellulose binding domain” that accelerates tree growth (superfast GM tree) would give hope to reforestation and damage control. The GM technology also opens the door for plant-based edible vaccines for preventable human diseases like tetanus, diphtheria, measles, and cholera. This cost-effective vaccine would have tremendous impact for global population health especially in developing and underdeveloped countries. For example, potato-derived hepatitis B vaccine would likely be the first edible vaccine that could save millions of lives.^[5]

As the public’s awareness of “green technology” is increasing, so does their reluctance of using harmful products. With biotech innovation, non-degradable toxic products are being replaced with biodegradable and less toxic products, and the applications are extended into plastics, food processing, textiles, polymers, and energy and mining industries. Environmental sector uses biotechnology in pollution control, waste management, and renewable resource areas. Although the use of transgenic in bioremediation is limited, the potential could be substantial in the foreseeable future. Biotechnology can also be applied in the conventional fossil fuel and renewable energy sector. For instance, a non-toxic biopolymer of xanthan gum and cellulose avoids the problems of conventional drilling mud via better viscosity and binding in the drilling process. The production of renewable fuel-like ethanol can be achieved more efficiently by using modified cellulase enzyme that maximizes the conversion of cellulose into fermentable sugar and in turn helps in reducing greenhouse gas emissions.

Biotechnology is extensively used in the food and food processing industry. A range of essential food products and food additives requires microbes or microbial source. *Lactobacillus*, *Streptococcus*, and *Leuconostoc* are commonly used in dairy industry for flavor, consistency, and reducing spoilage time. Various techniques have been used to modify the functional properties of foods such as spreadability of butter and enhancement of fruit and vegetable qualities. Fermentation technology is the other key area of this applied science. Although pharmaceutical and food industries rely heavily on the advancement of this technology, almost every sector has its use. Many important drugs, antibiotics, steroids, vaccines, hormones, enzymes, diagnostic products, solvents, food and food processing products, animal feeds, animal vaccines, biopesticides, and inoculants are the results of this technology. Improvements on bioreactors, computer-

controlled fermentation processes, and downstream processing have added a new dimension to the biotech industry. With the evidence of new diseases and many recurring diseases, the drug and pharmaceutical sector is rapidly expanding in areas of antibiotics, vaccines, hormones, enzymes, and diagnostic tests using monoclonal antibodies. Biotechnology also makes it possible to mass-produce these substances that might otherwise be cumbersome and expensive to produce. New methods allow producing purer drugs like human insulin from GM bacteria that does not cause any allergic reactions on patients. Evidently, biotechnology is becoming more diverse in application and beginning to make substantial contributions to the health and well-being of our society.

DILEMMAS AND CONCERNS

Like any other science, biotechnology is also not free from some obvious concerns. Environmental release of transgenes can impact food safety, human health, and environment because of its vast applications in the food and agricultural industry. There is also public perception that the use of GM products or continued biotech research is ethically or morally wrong. Whether they are scientifically based or not, it is important that all these issues need to be carefully considered.

Herbicide and Insecticide Resistance

The possibility of transferring transgenes from GM crops to wild relatives to create “superweeds” and insects that have developed tolerance to insecticides to create “superbugs” is not an unreal threat. Herbicide-resistant crops are voluntarily coming up in different fields creating huge problems. However, agronomic practices like crop rotation, hybrid rotation, and integrated pest management could reduce these risks.

Transfer of Allergens

To develop soybeans with higher methionine content, a Brazil nut gene was inserted, which is responsible for methionine-rich protein, into soybean. The transgenic soybean was supposed to be utilized as animal feed. But the product was found to be allergenic, and the soybean was never put on the market.^[6] StarLink corn was released for animal feed only. The corn contains Cry9C protein, a potential allergen. The genes were found in human food and seed corn causing many corn-based foods to be recalled although no health problems associated with the corn is reported.^[4] However, there is a real concern of accidental mix-up with the human foods.

Antibiotic-Resistant Genes

Antibiotic-resistant genes originally isolated from bacteria are used as selectable markers for transforming plants. By the use of such genes, cells that have been modified can grow in the presence of specific antibiotic, for instance, kanamycin-resistant corn. If these genes are transferred into human or other bacteria, they may increase antibiotic resistance in human or bacterial population. As such worldwide, an estimation of \$9 billion is wasted each year on ineffective use of antibiotics.^[7]

Gene Escape and Genetic Pollution

Preventing the movement of transgenes to the other plants is a concern for biotechnologists to avert the genetic pollution. There are some gene containment techniques like male sterility, terminator technology, apomixis, cleistogamy, chloroplast transformation, and transgenic mitigation, which can reduce gene transfer,^[8] but these are used for theoretical or laboratory purposes only.^[9]

Social, Moral, and Ethical Issues

Multinationals have heavily invested in biotechnology, and they would naturally want a return on their investment. This is a legitimate concern to think that these companies will either enforce technology fees or monopolize the marketplace. However, studies have revealed that farmers also enjoy a financial benefit from GM crops.^[6] This is mainly because of less pesticide use and enhanced production. In Canada, GM canola farmers experienced a 40% reduction in herbicide costs and a 10% increase in yield.^[10] Besides, other issues like increased reliance on developed countries by developing countries, control of food production by a special few, foreign exploitation of natural resources, and infringe on the natural organism's inherent traits are of great concern.^[3] Does it morally right to do gene transfer from bacteria to plant, animal to another animal, and human to animal? Are these ethically correct? These dilemmas are warranted rationale answer.

CONCLUSION

Although there are several GM products commercially available, biotechnology has no magic solution to all our problems. It has tremendous promise, but to attain its full potential it must be environmentally compatible, economically viable, and socially responsible. This is an ever-emerging technology that needs proficient management of its development. However, biotechnology may be the single most sought-after tool at our disposal capable of making significant contribution toward the food security and sustainable development.

Boreal Forest

Galina Mazhitova

Komi Science Center, Russian Academy of Sciences, Syktyvkar, Russia

Abstract

This entry is based on English and Russian publications and deals with soils of the circumpolar boreal biome, including the Subarctic forest–tundra and sparse forest. Environmental conditions are described. Major features of soil formation under boreal conditions, geographical distribution of soils in major boreal regions, land use, and global ecological significance of boreal soils are discussed.

INTRODUCTION

The boreal forest or taiga is a northern forest dominated by conifers (Fig. 1). The forest dominates the boreal biome, where it alternates with bogs and other ecosystems. The biome is circumpolar in the northern hemisphere (Fig. 2), and it is subdivided into low boreal, mid-boreal, and high boreal. The transition between the high boreal and the Arctic composed of forest-tundra/sparse taiga is called the Subarctic. Besides plains and lowlands, the boreal forest occupies a number of mountain systems: the Fennoscandian Range, the Ural Mountains, the mountains of southern and northeastern Siberia, and the northern extent of the North American Cordillera. The boreal forest covers 58.6 Mha in Scandinavia, 709.0 Mha in the Former Soviet Union, 42.4 Mha in Alaska, and 221.8 Mha in Canada.^[1–6] In addition, the Subarctic comprises 340.0 Mha in Russia and 171.2 Mha in Canada.^[4,6]

ENVIRONMENTAL CONDITIONS

Large boreal regions, with the exception of East Siberia, experienced multiple continental ice sheets in the Pleistocene, which predetermined the prevalence of geologically young parent materials and distribution of periglacial phenomena. Climate was highly dynamic during the Holocene, causing shifts of the northern tree line and southern border of the permafrost and the polygenetic nature of many subarctic soils.^[7,8] The northern tree line roughly corresponds to the July isotherm of 10°C. The climate of the boreal forest is characterized by long, cold, and snowy winters; however, it varies widely across the biome (Table 1).^[9–13] East Canada is humid with relatively mild winters, whereas East Siberia is semiarid and reveals the highest thermal continentality on earth. Either continuous or discontinuous permafrost

occurs everywhere in the Subarctic and in the closed taiga of East Siberia and Alaska. The rest of the biome is characterized by seasonal ground freezing. The most widely distributed boreal forests in the world are larch forests; in Russia, they occupy 269 Mha.^[14] Other important tree species are spruce, pine, fir, and birch.

SOIL CLASSIFICATION

In terms of Soil Taxonomy, the boreal biome comprises the largest area of Spodosols and Histosols, is the only biome where the Arctic and Alpine contain Gelisols, and is an important area of Alfisol formation. Inceptisols are also widespread. In terms of the world reference base (WRB) for soil resources, the boreal biome contains most of the Albeluvisols, Podzols, and Histosols and the second largest area of Cryosols after the Arctic. Luvisols, Cambisols, Gleysols, Regosols, Leptosols, and Fluvisols also occur.

MAJOR FEATURES OF SOIL FORMATION

Most soils in the boreal biome either are Gelisols, i.e., permafrost-affected soils, or have cryic thermal regime. Aquic or udic soil moisture regimes are common. Ice-cemented permafrost, where present, adds to soil saturation. In East Siberia, however, salts accumulate in some soils as a result of the semiarid climate. The cold climate hinders chemical weathering. The combinations of moisture regime, low pH, and non-neutralized organic compounds foster leaching, clay illuviation, and podzolization in many soils. The latter, though not confined to the boreal biome, is best pronounced and widely expressed throughout it. Permafrost and, in many regions, seasonal frost cause various cryogenic features in soils. Nutrient turnover is slow. Only a small fraction of the ecosystem nutrients are contained in the vegetation, and

Fig. 1 Mid-boreal spruce forest in European Russia.

Source: Photo courtesy of E. Lopatin.

the most are contained in soils.^[15,16] The most biologically active nutrient fraction is cycled in litterfall to the forest floor. In the Subarctic, because the trees are shallow rooted, the forest floor is the main source of nutrients for tree growth. However, boreal ecosystems are well adapted to the conditions of their growth. Conifers

need a small amount of nutrients and are able to grow on highly leached acid soils. About half of the world's wetland area is in the boreal biome, and most wetlands are bogs, that is, their soils are Histosols and Histels. In the area of continuous permafrost, peat plateaus and polygonal peatlands are typical. In the discontinuous permafrost area, palsa peatlands develop, and in the zone of seasonal frost, string mires and domed bogs are characteristic.^[17,18]

SOILS OF THE MAIN BOREAL REGIONS

Scandinavia

Spodosols, mostly typic Haplocryods, and Histosols dominate the soil cover. Many Spodosols in Lapland are cryoturbated, possibly in the absence of permafrost. Frost heave occurs everywhere in the region of the seasonal frost in Finland. The only Gelisols recognized are sphagnum or terric fibristsels in the palsas of Lapland.^[17]

European Russia

Cryalfs and, in the northern taiga, Aqualfs (Albeluvisols in terms of WRB) on loamy materials^[19] and Spodosols derived from coarse-textured parent materials^[20] dominate the area with small inclusions of Histosols (Sphagnum domed bogs). Similar to Scandinavia, no mineral Gelisols form within the biome; however, Histels develop in the forest-tundra under peat plateaus or palsas. West-facing slope and foothills of the Ural Mountains support the least human-affected boreal forests in Europe, which grow on Cryalfs and Cryepts.

West Siberia

West Siberia contains one of the world's largest lowland areas (128 Mha). Continuous permafrost occurs in the forest–tundra and is discontinuous in the northern taiga. Soils of the region have never been classified according to the Soil Taxonomy, except for several pedons in the Subarctic.^[21] The analysis of Russian literature^[21–23] indicates that not only histels but also mineral Gelisols develop in the Subarctic and in the east of the high boreal. To the south of these areas, Cryalfs and Cryods dominate well-drained sites, whereas Cryaqualfs and Cryaquods with deep albic horizons and often ortstein develop in poorly drained sites affected by groundwater. String-and-fen bogs with fibrists and hemists are typical for permafrost-free areas.

Central and East Siberia

The largest part of East Siberia has continuous low-temperature permafrost and is dominated by Gelisols.^[24–26] The Russian soil classification^[27] recognizes the soil type “Cryozem,” which is widely distributed here (oxyaquic Cryosols in WRB; typic haploturbels in the Soil Taxonomy). Oxyaquic features develop in fine-textured materials due to the presence of oxygen in the water of melting ground frost aided by the drainage provided by frost cracking.^[28] In Central Yakutia, unique haglels showing evidence of solidification develop.

Alaska

Eighty percent of boreal Alaska has sparse or discontinuous permafrost. Turbels, with some haglels and histels,

dominate permafrost-affected areas. Haplocryods and Humicryods are common for the Cordillera in south-eastern Alaska, whereas in southern Alaska, Andisols are the dominant soils.^[29]

Canada

About 30% of the land area in the Subarctic is covered with wetlands.^[18] In the continental high subarctic region, most wetlands are affected by permafrost, and their soils include histels. In the areas adjacent to Hudson Bay and in the east of the Canadian Subarctic, unfrozen fen and palsa complexes are common with fibrists, hemists, and histels. In addition, mineral Gelisols (both haglels and turbels) develop here as opposed to more southern boreal regions.^[29,30] South from the Subarctic, Cryepts and to a smaller extent Cryalfs dominate the western part of the territory with more Spodosols and Cryalfs dominating the eastern part.^[31]

LAND USE

The main use of boreal lands is for forestry. In Scandinavia, large areas of Histosols are artificially drained to cultivate forests. Main agricultural use is for seasonal pastures, with very small areas of ploughed lands. In major economic divisions of European Russia, the area of ploughed lands varied in 1981 from 8% to 39%,^[32] whereas it was incomparably smaller in Siberia. Most boreal soils are acid and nutrient poor and require liming and organic and inorganic fertilizers to grow crops.

GLOBAL ECOLOGICAL SIGNIFICANCE OF BOREAL SOILS

Global change ecological relationships within the taiga could assume global importance, because the biome greatly affects the world's carbon balance. Boreal forests contain 200 Pg organic carbon in soils, which is three times more than the estimated biomass pool.^[33] This accounts for 15% of global terrestrial detrital carbon pool.^[34,35] In the past, boreal regions, along with the Arctic ones, have been the net sink of carbon. This is primarily due to slow decomposition of soil organic matter. However, under global change, the biome's carbon pool is one of a few most vulnerable carbon pools in the Earth system. The boreal forest may become a major source of carbon due to anthropogenic activities and the increased rate of decomposition due to soil warming.

CONCLUSION

The boreal forest or taiga dominates the boreal biome, where it alternates with bogs and other ecosystems. Boreal biome is circumpolar in the northern hemisphere with large areas in both Eurasia and North America. Most boreal soils are permafrost affected or experience seasonal freezing. The boreal biome has the largest area of Spodosols and Histosols, is the only biome where the Arctic and Alpine contain Gelisols, and is an important area of Alfisol formation. The main land use of the boreal biome is forestry. Agricultural land use is limited to seasonal pastures and small areas of crop lands. Global change ecological relationships within the boreal biome could assume global importance, because the biome greatly affects the world's carbon balance. Three-fourth of the biome's organic carbon is located in soils.

Abstract

Boron (B) and molybdenum (Mo) are among the chief micronutrients essential for plant growth that exist in soil solutions as anions. B deficiencies occur in many countries of the world with coarse-textured soils in humid regions where leaching and heavy cropping have diminished the soil B reserves. B toxicity occurs in soils which are inherently high in B or as a result of high B fertilization. Mo deficiencies are common in many countries where soils are acidic and coarse in texture. Mo toxicities in crops tend to be rare in distribution and occur only when unusually high quantities of Mo are present.

INTRODUCTION

Boron (B) and molybdenum (Mo) are among the chief micronutrients essential for plant growth that exist in soil solutions as anions. B deficiencies occur in many countries of the world with coarse-textured soils in humid regions where leaching and heavy cropping have diminished the soil B reserves. B toxicity occurs in soils which are inherently high in B or as a result of high B fertilization. Such may be the case, e.g., if a B sensitive crop were to follow a crop that received a high rate of B, or through the use of irrigation water high in B. Crops sensitive to B, e.g., peanuts (*Arachis hypogaea* L.), could result in B toxicity^[1] at B levels as low as 2 kg ha⁻¹.^[2]

Mo deficiencies are common in many countries where soils are acidic and coarse in texture. Mo toxicities in crops tend to be rare in distribution and occur only when unusually high quantities of Mo are present. Soils high in Mo have been reported on some poorly drained soils, e.g., in Australia, Scotland, and the United States.^[3]

SOIL FACTORS AFFECTING PLANT UPTAKE

Boron

Soil reaction and pH

Generally, B becomes less available to plants with increasing soil pH. Visual symptoms of B deficiency were found to be accentuated by calcium (Ca) deficiency and were less evident when Ca was added in excess.^[4]

Macronutrients

Nitrogen (N) is of utmost importance in affecting B uptake by plants. Liberal N applications have been found to decrease plant B uptake. Increasing rates of phosphorus (P) and potassium (K) have also been found to decrease B uptake.

Soil properties

Higher quantities of available B are generally found in fine-textured than in coarse-textured soils. The lower amounts of B in sandy soils are associated with higher leaching of B. Organic matter is one of the chief sources of B in acid soils, as relatively little B adsorption occurs at low pH. Irrigation waters with high B can result in B toxicity in crops. B applied in bands is more effective than when applied broadcast in increasing B uptake by crops. Method of plowing (e.g., with moldboard plow) and ridge till resulted in higher B in plants than with no till and beds.^[5] Highly weathered acid soils are also responsible for causing B deficiency.^[6]

Other factors include environment, genotypes, and plant species, e.g., legumes can accumulate more B than grasses.^[7] Plant age and plant parts can affect the B composition of plants.^[8]

Molybdenum

Parent material and soil pH

Soils formed on sandstones that have experienced heavy leaching losses are most likely to be low in total

Mo. Alfisols derived from mixed shale may be higher in Mo than Spodosols formed from mixed schist. Lateritic soils derived from granite and basalt rocks are very high in total Mo. Soil solution MoO_4^{2-} is the most available form to plants. Its availability increases a hundredfold for each unit increase in pH. Alkaline soils have a relatively large proportion of Mo in the soil-solution phase. Some studies^[9] have indicated that the severity of Mo deficiency in lentil (*Lens culinaris* Medic) can be reduced by liming on Mo-deficient acid alluvial soils.

Soil properties

Coarse-textured loams and silty loams low in organic matter, as well as severely eroded and/or heavily weathered soils, are particularly low in Mo. The amount of Mo adsorbed may be closely related to the organic matter content. Soil wetness is one of the chief factors affecting the availability of Mo. Peats and mucks are products of a wet environment and have been associated with high Mo in certain regions of the world. Well-drained soils, e.g., podzols, are low in Mo. The availability of Mo to plants is also reduced by sulfur fertilization.

PHYSIOLOGICAL ROLE, DEFICIENCY, AND TOXICITY SYMPTOMS

Boron

B plays a key role in seed production. B deficiency can severely impede seed production particularly in legumes.^[10] B is involved in the transport of sugars across cell membranes and in the synthesis of cell wall material. Some studies suggest that the selection of transgenic cultivars with an increased sugar alcohol content can result in increased B uptake by translocating it as a complex sugar alcohol in the phloem.^[11] It promotes the elongation of epicotyls and hypocotyls and increased height of seedlings grown under aluminum stress.^[12] B deficiency can inhibit the growth of seedlings.^[13] B plays an important role in maintaining the integrity of plasma membranes of leaf cells and in alleviating the damage of membrane caused by low temperatures.^[13]

B deficiency in crops is more widespread than the deficiency of any other micronutrient. Because of its slow mobility in plants, B deficiency symptoms generally first appear on the young leaves at the top of the plant. Crops most sensitive to a B deficiency include rutabaga (*Brassica napobrassica* L.), other brassicas, forage legumes, and root crops.

The B toxicity symptoms are also similar among most plants. Generally, they consist of marginal and tip chlorosis, which is quickly followed by a necrosis.^[8]

Molybdenum

Mo is an essential constituent of several important molybdoenzymes. Nitrate reductase, which is involved in nitrate reduction in plants, and nitrogenase, which is involved in N fixation by legumes, are most important. Studies on beans in Brazil showed that foliar applications of Mo greatly enhanced nitrogenase and nitrate reductase activities resulting in increased N content in the shoots.^[14] Their results demonstrated that in certain soils, N fertilization may be replaced by small amounts of Mo as foliar application. Other roles of Mo include increased organic N, protein content, and drought resistance of plants. Lack of Mo can inhibit tasseling in corn and decrease sucrose and ascorbic acid concentrations in cauliflower (*Brassica oleracea* L. Botrytis Group) and legumes.

Deficiency symptoms for most micronutrients appear on the young leaves at the top of the plant because most micronutrients are not readily translocated. Mo is an exception in that it is readily translocated, and its deficiency symptoms generally appear as yellowing of the whole plant. Symptoms associated with Mo deficiency are closely related to N metabolism. In brassicas, Mo deficiency can result in cupped leaves, i.e., rolling or upward curling of leaves. Crops that commonly suffer due to Mo deficiency are forage legumes, brassicas, and soybeans [*Glycine max* (L.) Merr.]. Mo toxicity in crops is uncommon and is found only when unusually high concentrations of Mo are present. The most striking symptom of Mo toxicity as reported in alfalfa (*Medicago sativa* L.) is yellow or orange-yellow chlorosis, with some brownish tints that start in the youngest leaves. Further symptoms of Mo toxicity damage include moribund buds, thick stems, and development of axillary buds and sometimes succulent older leaves. Details of Mo deficiency and toxicity symptoms can be found elsewhere.^[3]

METHODS OF CORRECTING DEFICIENCY

Boron

Sodium borates of varying degrees of hydration and H_3BO_3 are principal sources of B fertilizers. Application rates of B generally range from 0.25 to 3.0 kg ha⁻¹ depending on crop requirements and the method of application. Higher rates are required for broadcast applications than for banded soil application or foliar sprays. On clay loam soils, rates of up to 8.8 kg ha⁻¹ are not toxic, while on sandy loam soils, this rate was toxic to cauliflower.^[15] However, on crops such as peanuts, sensitive to excess B, 2 kg B ha⁻¹ was found to be toxic.^[1] Grasses are highly tolerant of B, e.g., 45 kg B ha⁻¹ caused only 12% yield reduction.^[16] Most B sources are applied to soils with NPK fertilizers, and B may be incorporated or bulk blended with granular fertilizers or mixed with fluid fertilizers.^[17]

Table 1 Sufficiency levels of B and Mo in several crops.

Crop	Plant part	Sufficiency level (mg kg ⁻¹)	
		B	Mo
Alfalfa	Whole tops	20–40	0.12–1.29
Cauliflower	Leaves	11–97	0.19–0.25
Corn	Leaves	10	0.20
Red clover	Whole tops	21–45	0.3–1.59
Rutabagas	Leaves	40	—
Soybeans	Leaves	—	0.5–1.0
Wheat	Boot stage tissue	8	0.09–0.18

Source: From Gupta.^[3,8]

Molybdenum

Methods of controlling Mo deficiency in crops include band or broadcast application (generally of Mo contained in P or NPK fertilizers) to soil, foliar sprays, and seed treatment. Amounts applied to soil range from 50 g to 1 kg ha⁻¹ depending on the crop and soil pH. However, seed treatment is the most common method because the recommended rates are low, ranging from 50 to 400 g ha⁻¹. Mo sources can be applied to seeds as liquid or slurry, and some type of sticking or conditioning agents may be included. Because legume seeds, such as soybeans, peas (*Pisum sativum* L.), alfalfa, and clovers (*Trifolium* spp.), are treated with a bacterial inoculant, the Mo source for seed treatment must be compatible with the inoculant. Foliar rates of application range from 60 to 218 g Mo ha⁻¹.^[18,19] It should also be pointed out that on soils containing adequate Mo, liming soils to pH 6–6.5 can overcome a Mo deficiency in crops. Sufficiency levels of B and Mo for a few crops are shown in Table 1.

Brick Making: Soil Degradation

G.S. Dheri

Babu S. Brar

Debankur Sanyal

Department of Soil Science, Punjab Agricultural University, Ludhiana, India

Abstract

Bricks, a primary tool of urbanization, are made of soils. In the age of urbanization, a large amount of bricks are needed, which in turn destroy agricultural soils. Due to desurfacing, the most fertile portion of a soil profile is getting degraded. Most importantly, soil organic matter along with primary nutrients, such as nitrogen, phosphorus, and potassium, is lost from the soil, destroying soil microbial activities and depleting soil fertility as well as productivity. Hence, this important but ignored aspect of land degradation needs comprehensive studies to understand the extent of problem and remedial measures. In this entry, economic cost of nutrients lost due to desurfacing is estimated. Some management strategies for rehabilitation of desurfaced soils have also come up from few studies. Further studies will reveal more unknown facts about soil degradation by brick making and its management.

INTRODUCTION

Bricks, the cells of urban society, are made of a very common material, soil. Land, a gift of nature, we use it to grow foods and also modern, developed society. In this 21st century, we need more and more bricks to build more and more houses, in order to shelter the expanding population. But we have neglected a crucial part here. We are using a large amount of fertile agricultural soil to make bricks, degrading our lands, and thus converting fertile land to barren. Few studies have also been done on this aspect, several projects have also been started, but this alarming situation is quite neglected. A time has come to take a look at the scenario.

Ministry of Food and Agriculture, Government of India (1962) defined the term “land degradation” as “the lands available for cultivation but not taken up for cultivation or abandoned after a few years for some reason or other.” Land degradation can be considered in terms of the loss of actual or potential productivity or utility as a result of natural or anthropogenic factors.^[1] The widespread existence of brick kilns in the rural–urban fringes of the third world cities represents one of such important centers of anthropic activities with a potential to alter the ecology of the surrounding vegetation and soil.^[2] From 1958 to 2009, this has led to a decrease of agricultural area in the core zone of the cities by 60%.^[3] Accordingly, demand for construction materials, such as bricks, has increased as their production provides an employment opportunity for the urban poor.^[4] In India, bricks are usually made of clay and are generally produced in traditional, unorganized small-scale industries. Brick industries are essential for economic development, as they provide employment to nearly 12 million people.^[5]

Millions of hectares of lands and tons of carbon, nitrogen (N), phosphorus (P), and microbes are being losing every year through brick making, which not only destroying the agriculturally most important topsoils but also hindering microbially mediated essential soil processes and inducing the global warming and greenhouse effects.^[6]

DETRIMENTAL EFFECTS ON SOIL PROPERTIES AND NUTRIENTS

After the removal of surface soil, a very low-quality soil, characterized by high strength, very low permeability, and poor fertility, remains. Common crops, even weeds grow poorly on this soil. Degradation affects the productivity^[7] and this may be assessed in a number of ways. First, nutrients are lost in sediment and runoff. Generally, nutrients associated with organic matter, i.e., N, P, and the cation exchange of soil colloids, such as potassium (K) and calcium, are most at risk.^[8] Secondly, as soil degrades, its infiltration capacity worsens and consequently, there is drastic change in depth to water level. Few selected herb and shrub species can grow on burnt soil due to brick industry.^[9] Removal of plants’ cover and litter exposes soil to increased kinetic energy of rain drops, causing soil movement as well as increased erosion.

The greatest loss is undoubtedly removal of nutrients, as most of the available nutrients and organic carbon remains at the surface. In a study, it has been shown that brick kiln dust is alkaline with pH ranging from 8.2 to 10.5^[10] which in turn makes the neighboring soil pH higher. Desurfacing decreased organic carbon from 0.47% to 0.31%. Bulk

density values for 0–15 cm and 15–30 cm depths in desurfaced soil were greater than adjoining normal soil whereas available P and K were decreased.^[11] In a different study, it has been reported that the average loss of valuable soil components due to burning of the agricultural topsoils amounted to 63% for soil organic matter, 56–86% for total N, and 23–88% for total P, K, and S, respectively.^[12] The content of soil microbial biomass carbon was several fold higher in the unburnt (agricultural land) soil profiles than those of the burnt (soil around brick kilns) profiles, regardless of regions, climate and plant types or vegetation.^[6] According to a report by Grewal and Kuhad,^[11] due to desurfacing, the pH increased from 8.1 to 8.4, electrical conductivity decreased from 0.79 to 0.15 dSm⁻¹, organic carbon from 0.48% to 0.34%, available P from 3.56 to 1.78 kg ha⁻¹, and available K from 470 to 320 kg ha⁻¹.

Desurfacing of soil reduced available water holding capacity^[13] and deteriorated aggregate stability as compared with normal soil which may be attributed to lower soil organic matter, reduction of total porosity, and poor soil structure.^[14] Crop grown on desurfaced soils had small plant height, plant population, and yield.^[11,15–17] Additional application of fertilizers to compensate the fertility differences between normal and degraded soils was not able to sustained yield loss.^[17] Field adjacent to desurfaced soils remained at high risk of erosion during rainy season and irrigation.^[18]

GLOBAL SCENARIO OF BRICK MAKING

A study by Narayan and Gupta^[2] revealed that a huge chunk of agriculturally fertile lands are consumed by each brick kiln (3–4 ha), which get converted into wastelands as a result of industrial operation in the life of a brick kiln (8–12 yr). There are approximately 1,00,000 large-scale kilns with fixed chimneys, ca. 1,900 operating in India and 6,000 in Bangladesh. Latin America also has a considerable number of brick production facilities, including 6,898 in Brazil, 300 in Chile, 2,453 in Colombia, 17,000 in Mexico, and 2,222 in Peru.^[19] About 1,500 billion bricks are produced every year, 1 billion of those are produced in China and altogether Asia generates almost 90% of global production.^[13]

ECONOMIC IMPACTS

Economic impacts of soil degradation through brick making can be estimated using two approaches, that is, replacement cost approach (RCM) and productivity changes approach (PCA). The estimated economic costs of desurfacing the soil for brick making using PCA were higher compared to RCM, due to the ignorance of PCA to the loss of certain unquantifiable, qualitative properties of topsoil which lead to yield loss.^[20] Francisco and Angeles^[21] developed relationship between corn yield and soil loss ($Y_t = 1,360 - 12.5 \times \text{soil loss}$) and estimated that

Table 1 Annual loss of nutrients in brick making.

Nutrients ^a	Loss per brick (g)	Total amount lost (Tera g)	Total monetary loss (approximately)	
			Rs. ^a (billion)	\$ ^a (billion)
N	15–45	22.5–67.5	264.15–792.45	4.40–13.21
P	0.3–6	0.45–9	52–1040	0.86–7.18
K	0.6–6	0.9–9	30.13–301.32	0.50–5.04

^aThe the source of N is urea (46% N) at Rs. 541 per quintal, source of P₂O₅ is single super phosphate (16% P₂O₅) at Rs. 800 per quintal and the source of K₂O is muriate of potash (60% K₂O) at Rs. 1670 per quintal and it is assumed that 1\$ = Rs. 60.

corn yield decline equivalent to 12.5 kg ha⁻¹ with a ton of soil loss.

It was found that for making one brick, approximately 3 kg of clay is used and production of 47 bricks leads to degradation of 4 ft² land.^[22] So, if it is assumed that an agricultural soil contains about 0.5% organic carbon on an average, then, about 22.5 tera g (1 tera = 10¹²) of organic carbon is being lost from soil due to brick making annually as per reports mentioned. In general, for a normal fertile soil, the values of N, P, and K are in the range of 0.5–1.5%, 0.01–0.2%, and 0.02–0.2%,^[23] respectively, and the calculated loss of nutrients in amount and monetary terms are presented in Table 1.

MANAGEMENT STRATEGIES

Soil desurfacing to make bricks is increasing exponentially posing a threat to soil protection and soil productivity. Rapid restoration of soil productivity and management of desurfaced soils are of great concern but generally neglected. Desurfacing makes the soil unsuitable for crop production as subsoil horizons that are generally rich in calcium carbonate, high in bulk density, and poor in organic carbon, available nutrients, biological activity, and available water holding capacity are exposed to the surface.^[11] The first step in designing proper management techniques is to point out the dominant factors that limit crop production. The renovation of soil structure through organic amendments and agronomic practices or their integrated use is considered to be useful for the amelioration of desurfaced soils. Because available nutrient status is poor in desurfaced soils, use of higher doses (about 25% to 50% more) of fertilizers and water than that of normal soils for better crop growth can be beneficial. Alternative uses of desurfaced soils for social forestry, soil waste disposal, farm ponds, etc., need to be explored.^[11] Desurfaced soils can be effectively revived by using organic manures (poultry manure, animal waste, press mud, farmyard manure, and vermicompost); incorporation of crop residue and biochar; adopting green manuring and leguminous crops in crop rotation, deep tillage, gypsum application; using bio-fertilizers,

social forestry, fishery ponds, balance fertilization and extra 25–50% supplementary doses of fertilizers.^[24] Remote sensing data coupled with analytical and field-based data are useful in proper planning for management of degraded soils. Interpretation of satellite imagery recognizes brick kilns spatially that open way for management using other data toward sustainable development in the area.^[9] Such interdisciplinary approach for management of degraded soil could be useful for any area.

CONCLUSION

One thing is clear from the discussion, scientists have to find a way to defend this enormous destruction of fertile agricultural lands for making bricks. To support the ever-expanding population pressure, we are in need of more and more lands to produce foods and we cannot afford this huge loss of soil as well as nutrients. This aspect of land degradation is neglected throughout the world. Only limited studies have been conducted in this aspect. A lot of research is needed to find out better cropping systems, cultural practices, fertilizer managements, and agronomic practices in order to stepwise rehabilitate the degraded agricultural soils.

Bulk Density

Kwong Yin Chan

Organic Wastes Recycling Unit, New South Wales Department of Primary Industries, Richmond, New South Wales, Australia

Abstract

Bulk density is a key soil physical property commonly used as an indicator of soil compactness, soil structure, and aeration status. It is also required for converting soil water content and nutrient values from the gravimetric to the volumetric basis. Depending on soil types, conditions of sampling, and degree of accuracy required, there are direct and indirect methods for the determination of bulk density.

INTRODUCTION

Bulk density (ρ_b) is defined as the ratio of the mass of a given soil sample (M) to its bulk volume (V) as follows:

$$\rho_b = \frac{M}{V} \quad (1)$$

The mass is obtained by drying the sample to a constant weight at 105°C, and the bulk volume is that of soil particles plus pore space at the time of sampling.^[1] The commonly used SI unit for bulk density is Mg/m³, which is numerically the same as g/cm³. Bulk density is a key soil physical property and is required for: 1) determining the degree of compactness and hence as a measure of soil structure; 2) using as an indicator of soil aeration status (together with soil water content); and 3) converting soil water content and nutrient values from the gravimetric to the volumetric basis.

Bulk density of soil depends on the composition as well as the structural conditions. It therefore tends to vary with the soil texture, which determines the packing of the soil particles. Sandy soils tend to have higher bulk density (ranged 1.4–1.9 Mg/m³) than clays (0.9–1.4 Mg/m³; Table 1). Volcanic soils and peaty soils tend to have bulk density <1.0 Mg/m³ because of the high organic matter levels and special clay minerals for the former and higher organic matter levels for the latter. Furthermore, as field soils are not just mixtures of primary particles in different degrees of packing, bulk density is also modified by soil aggregation (soil structure) and soil organic matter levels. Organic matter tends to reduce the degree of compaction. For 58 samples of surface soils in Scotland, a highly significant effect of organic matter is represented statistically by the following relationship:

$$\rho_{\max} = 1.86 - 0.055 \times \text{OM} \quad (2)$$

where $\rho_{\max}$ is the maximum bulk density over a range of 1.3–1.8 Mg/m³ and OM is the content of organic matter over a range of 2–10% that was obtained.^[3]

SOME RELATED TERMS

1. Wet bulk density (ρ_w) is the wet mass of soil per unit volume and is related to ρ_b as follows:

$$\rho_w = \rho_b(1 + \theta_g) \quad (3)$$

where θ_g is gravimetric water content, kg/kg soil.

- i. Porosity (ε) is the total pore space per unit volume of soil, m³/m³, and is related to ρ_b as follows:

$$\varepsilon = 1 - \frac{\rho_b}{\rho_s} \quad (4)$$

where ρ_s is soil particle density, Mg/m³.

- ii. Air-filled porosity (ε_a) is the air-filled pore space per unit volume of soil, m³/m³, and is related to ρ_b as follows:

$$\varepsilon_a = \varepsilon - \theta_v = 1 - \frac{\rho_b}{\rho_s} - \rho_b \theta_g \quad (5)$$

where θ_v is volumetric water content, m³/m³.

METHODS FOR DETERMINATION

Methods commonly used for bulk density determination can be grouped into the following two categories.

Direct Methods

Direct methods involve measurement of the sample mass and volume, following Eq. 1. The most widely used procedure is the “core method” in which a cylindrical sampler is hammered into the soil.^[4,5] As the volume of the cylinder is known, trimming of the soil core flush with the ends of the cylinder and drying of the soil at 105°C for determining its weight allows the bulk density to be calculated. Accuracy of the core method is affected by compression and

Table 1 Range of bulk density and porosity values in different soils and particle mixtures.

Soil/particles mix	Bulk density (Mg/m ³)	Porosity (%)
Surface soil of wet clay	1.12	0.58
Surface soil of loam	1.28	0.52
Sandy subsoil	1.61	0.39
Sandy loam compacted by heavy traffic	1.90	0.28
Spheres of uniform size in open packing	1.39	0.48
Spheres of uniform size in close packing	1.96	0.26
Sandstone	2.12	0.20
Peaty soil	0.3	—
Volcanic soil	<0.9	—

Note: For swelling soils, bulk density is a function of soil water content.

^aParticle density (ρ_s) is taken as 2.65 Mg/m³.

Source: Adapted from Marshall & Holmes.^[2]

shattering, which are dependent on sample size and soil water content.^[4,5] Samplers with too small diameter are unsuitable because of the risk of compression. A thin-walled sampler with the diameter of 75–100 mm has been proposed as a compromise.^[4] The core method works best in soft cohesive soils sampled at water contents in the region of field capacity. The method is not suitable for non-cohesive soils, i.e., sands, gravels, and gravelly soils. In the latter cases, excavation methods that involve digging a burrow in the soil and determining the volume of the hole (using rubber balloon or sand displacement methods) and the oven-dried weight of the excavated soil are preferred.^[5,6] For the sand displacement method, the volume of the hole is determined by filling it with sand from a precalibrated sand funnel.^[1]

For soil samples of irregular shape, e.g., clods and aggregates, bulk density can be measured using the “clod method” which involves coating with paraffin wax or resin (e.g., Saran resin) and liquid displacement for the determination of volume.^[4,5] Saran resin coating has been used for the determination of bulk density changes of swelling soils over a range of soil water contents on a single clod.^[7] As the resin has the unique property of being permeable to only water vapor molecules but not liquid water molecules, it allows the determination of shrinkage curve on one single clod, thus greatly reducing sampling variability.

With proper precautions taken, the field determination of bulk density using the core method has a relatively low coefficient of variation (<10%) for uniform soils.^[8] Therefore, about four samples should be sufficient to estimate the mean bulk density to within 10% of the true value, 95% of the time.

Radiation Methods

Radiation methods are based on the empirical relationships between radiation and soil wet bulk density. The most common methods involve the attenuation and scattering of gamma radiation by soil, both of which increase with bulk density.^[5] Because of the interaction of gamma radiation with water, simultaneous measurement of soil water content is required for the calculation of bulk density using Eq. 3. Radiation methods are potentially at least equal in accuracy to any of the direct methods^[5,9] and are simpler and quicker to use especially where measurements at depth are required. It has the added advantage of being non-destructive and therefore allows repeated measurements at the same location; however, the equipment is more expensive and involves safety issues associated with the use of radioactive radiation.

APPLICATION OF BULK DENSITY MEASUREMENTS

As Indicator of Soil Structure and Soil Quality

Bulk density has been included in a minimum data set for monitoring soil quality, as an indicator of both soil structure and soil strength.^[10] Changes in bulk density reflect changes in soil structure because of the relationship between bulk density and total porosity (Eq. 4). However, total porosity gives no indication of the pore size distribution and pore continuity, which are important attributes of soil structure and associated functions.^[11] Nevertheless, with the exception of swelling soils, soil compaction is often measured by the increases in bulk density. As bulk density of swelling soils changes with soil water content, comparison is only valid at the same soil water content.

Bulk density affects plant growth because of its effect on soil strength and soil porosity. With increasing bulk density, strength tends to increase and porosity tends to decrease; both tend to be limiting to root growth at some critical values. Critical bulk density for root growth was found to vary with different textures; e.g., for sunflower, the critical value was 1.75 Mg/m³ for sandy soil and 1.46–1.63 Mg/m³ for clays.^[12,13]

To account for the texture difference so that crop yield can be related to soil compaction (bulk density) over a whole range of soils, the concept of degree of compactness has been proposed.^[14] The latter refers to the ratio of the bulk density of the soil in the field to that of the same soil in a compacted reference state of 200 kPa. As an average of 100 field experiments on a range of soil types (%clay = 2–60%), the optimal degree of compactness for grain yield was 0.87 above which adverse effects start to occur.

As a Measure of Aeration Status

Together with gravimetric water content and using Eq. 5, air-filled porosity (ϵ_a) can be calculated. ϵ_a values ranging between 0.05 and 0.15 (m^3/m^3) are commonly used as the critical limit below which aeration is limiting to root growth.^[15]

Conversion of Gravimetric Data to Volumetric Data

Laboratory analyses for soil organic matter, nitrogen contents, water contents, and so on are commonly expressed on a gravimetric or weight basis; however, for comparison in the field in terms of management practices, the amount per volume of soil or per area is preferred. For the conversion, soil bulk density, which frequently varies with management, depth of sampling, and time of the year, is needed. For example, to calculate the mass of organic carbon (OC) in t/ha to 0.10 m depth from gravimetric OC (g/kg), the following equation can be used:

$$\text{OC(t/ha)} = \text{OC(g/kg)} \times \rho_b(\text{Mg/m}^3) \quad (6)$$

The inclusion of bulk density in a set of basic soil indicators for the proper interpretation of the change in magnitude in chemical and biochemical soil components has been proposed.^[10]

Estimate of Mass of Large Volume of Soil

To estimate total mass of soil in 1 ha of land to 0.10 m depth, knowledge of soil bulk density is needed

$$\text{Mass(t/ha)} = \rho_b(\text{Mg/m}^3) \times 1000 \quad (7)$$

CONCLUSION

Bulk density is a key soil physical property commonly used as indicator of soil compactness, soil structure, and aeration status. It is also required for converting soil water content and nutrient values from the gravimetric to the volumetric basis. Depending on soil types, conditions of sampling, and degree of accuracy required, there are direct and indirect methods for the determination of bulk density.

Bunch Planting: Water Conservation

B.A. Stewart

Department of Agricultural Sciences, West Texas A&M University, Canyon, Texas, U.S.A.

Abstract

Stored soil water and growing season precipitation generally support early season growth of grain sorghum (*Sorghum bicolor* L. Moench) in dryland areas, but severe water stress is the norm during the later growth stages. Consequently, grain yield is generally low. Further studies have shown that growing grain sorghum in clumps rather than being equally spaced reduces tillering and early season vegetative growth, thereby conserving more soil water for use during the later growth stages. This results in an increase in the harvest index and a higher yield of grain. The architecture of clumped plants is also notably different from uniformly spaced plants. The leaves of both the tillers and main stalk grow outward, exposing essentially all of the leaf area to sunlight and wind. In contrast, clumped plants grow upward with the leaves partially shading one another and reducing the effect of wind, thereby reducing water use.

INTRODUCTION

Significant gains have been made in storing more precipitation as soil water during fallow periods and increasing the use efficiency of growing season precipitation by leaving crop residues on the soil surface.^[1] The fact remains, however, that dryland crop production in many semiarid regions are severely constrained nearly every year by scarcity of growing season precipitation. Water becomes particularly lacking during the later growth stages for grain crops such as wheat and grain sorghum. The later stages are the reproductive and grain filling, and during these stages, yield and quality are drastically reduced without water. Craufurd et al.^[2] reported that water stress during the stages of booting and flowering resulted in grain yield reduction of up to 85% for grain sorghum.

Crops are often grown under hostile climatic conditions where water limits yield every year. In semiarid regions such as the U.S. Southern High Plains, average precipitation for every month of the year is less than one-half of the potential evapotranspiration. Therefore, growing dryland crops such as grain sorghum (*Sorghum bicolor* L. Moench) requires that a significant quantity of plant-available water is stored in the soil profile at the time of seeding to supplement the growing season precipitation. Grain sorghum is generally seeded in these areas during the time of year when the probability of precipitation is high so that plant establishment can be achieved. Thus, with the precipitation during stand establishment and the stored plant, available water in the soil profile, plant-growing conditions during the early growth stages are generally favorable. However, water stress during the reproduction and grain-filling stages occurs practically every year and results in low grain yields. Many farmers use low plant populations as a strategy for using less of the stored soil water during the early growth

stages so that more will be available during the later stages. This strategy is often not effective because widely spaced grain sorghum plants commonly produce one to several tillers that utilize water and nutrients early in the season but produce little or no grain, particularly in years when growing season precipitation is low. Therefore, most or all of the expected benefits of using low plant population are often negated.

Stewart^[3] and Bandaru et al.^[4] conducted studies to determine if growing plants in bunches, or clumps, would affect early season growth and subsequent grain yield when compared with uniformly spaced plants. They hypothesized that growing grain sorghum plants in clumps would result in fewer tillers and less vegetative growth so that more soil water would be available during the grain-filling period.

EXPERIMENTAL FINDINGS

A summary of the methods and results reported by Bandaru et al.^[4] relating to the hypothesis stated above is presented here. The treatments used in the 2004 study are shown in Fig. 1. The primary focus of the treatments was to determine how growing plants in clumps would affect tillering and water use during the season, and there was also a treatment where the tillers were removed by hand to provide information about whether plants growing in clumps with few or no tillers when compared with equally spaced plants with or without tillers. Similar studies were conducted for three different slope positions—upper, middle, and bench position. Runoff from the upper position ran across the middle position, and runoff from the middle position was captured on the bench position. Therefore, there were different water regimes for the three positions,

Fig. 1 Schemes showing plant geometries for the treatments used in the 2004 experiments at Bushland, Texas, and Tribune, Kansas.

but they were not controlled. The upper position was the driest, the bench position was the wettest, and the middle position somewhat in between them.

The results reported in Table 1 show clearly that plants growing in clumps produced significantly fewer tillers than equally spaced plants. Tillering is a complex phenomenon, and it is not clear why clumping reduced the number of tillers so dramatically. Studies have shown that the production of tillers is reduced, as the ratio of red to far red light is decreased.^[5–7] In Bandaru et al.’s^[4] study, clumped plants did not receive as much light at the base as individually spaced plants. Also, when there were four plants per clump, C4-100, there were fewer tillers produced than when there were three plants per clump, C3-75 (Table 1). This suggests that the amount of light at the base decreases as the number of plants in a clump increases.

Aboveground biomass and leaf area produced during the initial 42 days of growth were closely related to tiller production (Table 1). Treatment SP-25 produced ~75% more dry matter and leaf area than the C4-100 treatment. The SP-25-TR treatment that had the tillers removed as they were formed to produce essentially the same amounts of dry matter and leaf area as the C4-100 treatment, supporting the hypothesis that the increased dry matter and leaf area for the SP-25 treatment were the results of more tillers.

Notes: DAP, days after planting. Separate but identical experiments were conducted on three positions that had different amounts of stored soil water at the time of seeding and different amounts of runoff or run-on during the cropping season.

^aPlanting geometries were SP-25 (plants every 25 cm), C3-75 (clumps of three plants every 75 cm), C4-100 (clumps of four plants every 100 cm), SP-38 (plants every 38 cm), and SP-25-TR (plants every 25 cm with tillers removed by hand) in 75 cm rows.

^bMeans in columns for a position on the benched terrace followed by the same letter are not significantly different according to a protected LSD mean separation ($P < 0.5$ level); each position represents a separate experiment and cannot be compared statistically.

Source: Adapted from Bandaru, Stewart, et al.^[4]

Although there were large differences in the number of tillers for the various treatments (Table 1), the differences in the number of panicles produced were much smaller. This was because a large percentage of the tillers, particularly for the experiment located on the upper position of the benched terrace where water stress was more severe, did not produce panicles.

Grain yields were relatively high for experiments located on the bench position (Table 1) because this position received runoff from experiments located on other slope positions. There were no differences in yields between the clump treatments, C3-75 and C4-100, and the spaced plant treatments, SP-25 and SP-38, for experiments on the bench. However, the yield of the SP-25-TR

treatment that had tillers removed was reduced. This reduction was most likely caused by an insufficient number of panicles for the yield level achieved with the favorable water conditions.

The yield increase from clumped plants was primarily due to higher harvest indexes. This indicates that under water-stressed growing conditions, as is almost always the case in the semiarid regions like the U.S. Southern Great Plains, growing grain sorghum in clumps rather spaced uniformly reduces tillering and early season vegetative growth and conserves soil water until later in the season and may enhance grain yield. The benefit of clumps decreased as grain yields increased, and there was even a slight decrease when yields exceeded 6000 kg ha⁻¹. There was also a noted difference in the architecture of the plants. Uniformly spaced plants produced more tillers, and the leaves of both the tillers and main stalk grow outward, exposing essentially all of the leaf area to sunlight and wind. In contrast, clumped plants grow upward with the leaves partially shading one another and reducing the effect of wind, thereby reducing water use. Growing grain sorghum in clumps in semiarid areas as shown in Fig. 2 appears to be a useful strategy with little downside risk.

Fig. 2 Dryland grain sorghum growing in clumps at Bushland, Texas, in 2007.

CONCLUSION

Grain sorghum planted in clumps rather than spaced uniformly in rows in the semiarid dryland U.S. Southern Great Plains resulted in higher grain yields in years of lower than average precipitation. Tiller formation was reduced, and there was less early season vegetative growth conserving a greater portion of the stored soil water for use during the reproductive and grain-filling growth stages. This strategy may be applicable to similar dryland environments of the world.

Calcification

Janis L. Boettinger

Utah State University, Logan, Utah, U.S.A.

Abstract

Calcification is the general process by which calcium carbonate (CaCO_3) accumulates in soils. Most commonly, CaCO_3 accumulates in subsurface horizons of soils in subhumid, semiarid, or arid regions. The accumulation of CaCO_3 in subsoil horizons is often coupled with its removal from overlying horizons, linked by the downward translocation of the soluble ions that precipitate to form CaCO_3 . However, the properties and processes that govern water flow in soils also affect calcification. Calcification can operate at a rate and duration such that subsoil horizons become plugged with CaCO_3 , effectively limiting penetration by plant roots and reducing the conductivity of gases, solutions, and suspended solids. The objective of this entry is to describe the environmental factors, components, mechanisms, and manifestations of calcification in soils.

COMPONENTS OF CALCIFICATION

For calcification to occur in soil, there must first be sources of calcium carbonate (CaCO_3) or the ions that precipitate to form CaCO_3 . Calcium (Ca^{2+}) is the cation required, and bicarbonate (HCO_3^-) or, less commonly, carbonate (CO_3^{2-}) are the required anions.

The most direct source of CaCO_3 for calcification is calcareous soil parent materials, which already contain CaCO_3 . Examples include limestone,^[1] calcareous shales and sandstones, and unconsolidated sediments derived from calcareous rocks (i.e., alluvium and lacustrine sediments). However, calcification can occur in soils that lack obvious calcareous parent materials. A likely external source of CaCO_3 in arid and semiarid regions is the eolian deposition of fine-grained calcareous sediments onto the soil surface ("calcareous dust").^[2,3] These calcareous eolian sediments originate from areas rich in calcareous sediments that can be easily entrained by the wind, such as playas or basins that contain dry lake beds.^[4]

Calcium-bearing, primary silicate minerals may also be a source for the Ca in the CaCO_3 that accumulates in soil.^[5] Silicates that can weather to provide a source of Ca for calcification include plagioclase feldspars (e.g., anorthite, $\text{CaAl}_2\text{Si}_2\text{O}_8$; oligoclase, $\text{Na}_{0.8}\text{Ca}_{0.2}\text{Al}_{1.2}\text{Si}_{2.8}\text{O}_8$; etc.) and Ca-bearing amphiboles (commonly hornblende) and pyroxenes.

Carbon dioxide (CO_2) gas is the ultimate source of bicarbonate and carbonate in soils. CO_2 , which attains a higher partial pressure in soils than in the atmosphere because of respiration by plant roots and heterotrophic microorganisms, dissolves in water to form carbonic acid (H_2CO_3):

H_2CO_3 is a weak acid that dissociates to form bicarbonate (HCO_3^-) that dissociates very slightly to form carbonate (CO_3^{2-}):

The dominance of these species in soils depends on the pH. Bicarbonate is the dominant species in solutions of most soils, whereas H_2CO_3 dominates only in strongly acid soils and carbonate dominates only in strongly alkaline soils.

MECHANISMS OF CALCIFICATION

The first step in calcification is the chemical weathering of minerals in upper soil horizons. In soils that contain calcareous parent materials or receive calcareous eolian deposits, CaCO_3 must first dissolve. Some authors refer to this process as "decalcification."^[6] Dissolution of CaCO_3 is accelerated by the presence of weak acids in soil solution because (CO_3^{2-}) associates readily with H^+ to form (HCO_3^-). H_2CO_3 is the most common solvent of CaCO_3 in natural systems.^[7]

H_2CO_3 also accelerates the dissolution of primary silicate minerals in soils and other natural systems. For example, diopside, a Ca-bearing pyroxene ($\text{CaMgSi}_2\text{O}_6$), can undergo H_2CO_3 weathering in soil solution to produce Ca^{2+} and (HCO_3^-) as well as Mg^{2+} and silicic acid (H_4SiO_4):

Any process that increases CO_2 in the soil solution can increase the rate of H_2CO_3 weathering.

The second step in calcification involves the movement of Ca^{2+} and (HCO_3^-) ions in solution to the soil horizon(s) where the conditions allow the chemical precipitation of CaCO_3 . Because atmospheric precipitation is limited in arid and semiarid climates, products of mineral dissolution are not effectively leached from soils. Instead, Ca^{2+} and (HCO_3^-) generally move downward with percolating solutions to deeper soil horizons. However, soil properties and processes that affect the magnitude and direction of saturated or unsaturated water flow in soils will influence where CaCO_3 ultimately precipitates and accumulates. For example, the downward movement of soil solution may be inhibited by an underlying slowly permeable layer (e.g., clay-rich horizon or bedrock) or by a textural discontinuity (e.g., silt loam or loam overlying loamy sand or gravelly sand). Alternatively, the soil solution may move upward in response to a water potential gradient set up by abundant water in the subsoil, such as a seasonally high water table, and evapotranspiration of water from near-surface soil in arid, semiarid, or seasonally dry climates.

The third step in calcification involves the chemical precipitation of CaCO_3 ; this step is defined exclusively by some authors as the process of “calcification”.[6]

The removal of H_2O directly increases the concentration of Ca^{2+} and (HCO_3^-) in the soil solution and causes the precipitation of CaCO_3 . Decreasing the partial pressure of CO_2 will also enhance the precipitation of CaCO_3 . In the case of downward moving solution in arid and semiarid climates, deeper horizons of soils are generally drier and have lower partial pressures of CO_2 because of reduced biological activity. These conditions alone may favor the precipitation of CaCO_3 . However, the removal of H_2O by plant roots via transpiration directly causes the precipitation of CaCO_3 . Evapotranspiration of H_2O causes precipitation of CaCO_3 in soils in which the solution moves upward into drier horizons that have increasing concentrations of plant roots.

Soil microorganisms can play a direct role in the precipitation of pedogenic CaCO_3 .^[8] In soil horizons with Ca-rich solutions, some bacteria and fungi excrete excess Ca^{2+} . If the soil is sufficiently alkaline and moist, the CO_2 respired by heterotrophic microorganisms and plants dissolves and dissociates to form an abundance of (HCO_3^-) . Excreted Ca^{2+} combines with (HCO_3^-) in solution to precipitate CaCO_3 on the exterior surface of the microorganism.

The continued precipitation of CaCO_3 at about the same soil depth interval over hundreds or, perhaps, thousands of years results in the accumulation of CaCO_3 . CaCO_3 precipitates mainly in larger soil voids, which dry more quickly and have lower partial pressure of CO_2 than smaller micropores.^[9] CaCO_3 also acts as a template for further precipitation of CaCO_3 . The mineral form of pedogenic CaCO_3 is

almost exclusively calcite, including that which is microbially precipitated.^[8]

MANIFESTATIONS OF CALCIFICATION

The morphology of CaCO_3 concentrations is varied.^[2,10] Carbonates can be disseminated or finely dispersed throughout the soil matrix such that specific carbonate features are not visible. Carbonates can also be segregated into visible morphological features such as filaments, soft masses, concentrically layered concretions, and irregularly shaped nodules. Carbonates can occur as coatings and pendants (coatings restricted to the undersides) on sand grains and rock fragments.

The manifestations of accumulating CaCO_3 with increasing time are different in gravelly and non-gravelly soils.^[2] In gravelly soils, CaCO_3 first appears as thin, discontinuous coatings on rock fragments where water flows preferentially. With accumulation over time, coatings become continuous, followed by CaCO_3 filling in the interstices between rock fragments (Fig. 1). Eventually, CaCO_3 can plug the interstices and effectively cement the soil fabric, which reduces water, gas, and solute flow through the horizon. In non-gravelly soils, which possess smaller pores and a larger total pore volume, CaCO_3 is first disseminated, then appears as filaments and coatings on sand grains. Nodules of CaCO_3 form and increase in abundance and size with time. The soil fabric between the nodules eventually fills in with CaCO_3 , effectively plugging and cementing the horizon. At this stage, in both gravelly and nongravelly soils, the downward moving solution is restricted and CaCO_3 accumulates at the upper boundary of the plugged horizon, forming a very hard, laminated layer.

As mentioned before, the properties and processes that affect water flow in soils influence the patterns of CaCO_3 accumulation in soil. Similarly aged soils (ca. 13,000 years) formed in calcareous lacustrine sediments of Pleistocene pluvial Lake Bonneville in a seasonally dry climate exhibit different vertical distributions of CaCO_3 (Fig. 2).^[11] The different patterns of CaCO_3 accumulation are strongly influenced by different depths to a seasonally high water table. The dominant direction of water flow is downward in soils that are not influenced by a water table, and CaCO_3 removed from upper horizons accumulates near the average maximum depth of wetting (e.g., Parleys, Fig. 2). Much of the water movement is upward in soils that have a seasonal high water table near the soil surface, and relatively insoluble CaCO_3 accumulates at about the depth of the water table (e.g., Salt Lake, Fig. 2). Soils that experience downward percolation of water and have a seasonal water table present in the subsoil exhibit both removal of CaCO_3 from upper horizons and the precipitation and accumulation of CaCO_3 at about the depth that the downward moving solution and the water table meet (e.g., Nibley) (Fig. 2).

Fig. 1 Profile of a soil with CaCO_3 accumulation in the subsoil. The soil formed in the seasonally dry, semiarid climate in late Pleistocene-aged deltaic sediments derived from pluvial Lake Bonneville and alluvium. Carbonates occur as coatings and pendants on rock fragments and are disseminated between rock fragments. The CaCO_3 is concentrated below the textural discontinuity between alluvial gravelly loam and underlying deltaic very gravelly sandy loam and sand.

Abstract

Calcium (Ca) has numerous roles in soils, plants, microflora, and fauna. In particular, Ca influences soil chemical and physical properties, maintains the structure and function of the cell plasma membrane, and is directly involved in cell signaling (as a secondary messenger).

CALCIUM IN SOIL

The average Calcium (Ca) content in the earth's crust is about 36 g/kg.^[1] In contrast, the average Ca content in soils is around 10 g/kg, which is about five times lower than the Ca content in igneous and sedimentary rocks, reflecting the ease of Ca leaching in the weathering process and in well-drained soils. Calcium (Ca) in igneous and metamorphic rocks occurs mainly in the plagioclase series of feldspars, with the high end of the plagioclase series weathering rapidly. Non-calcareous soils contain Ca in the form of high sodium plagioclase, augite, hornblende, and epidote.^[2] These minerals weather slowly and therefore are not good sources of Ca for living organisms. Calcareous soils have been formed from limestone or marl parent materials and frequently contain 50% or more calcium carbonate, with little Ca leaching over time owing to arid climates.

Leaching of Ca from soils in wet climates can be substantial, amounting up to around 300 kg Ca/ha/yr. Some fertilizers (e.g., ammonium) can increase Ca^{2+} leaching by displacing Ca^{2+} from the soil cation exchange complex. Losses of Ca^{2+} from soils by leaching are generally greater than the amounts taken out in farming products.

Exchangeable Ca

The crystallographic (dehydrated) radius of Ca^{2+} cation is 0.099 nm, which is smaller than the radii of soil monovalent cations and many divalent cations (e.g., Sr^{2+} and Ba^{2+}) but not smaller than the magnesium ion (Mg^{2+}) radius (0.066 nm).^[3] However, the hydrated radius of Ca^{2+} (0.43 nm) is greater than that of monovalent cations and is also greater than the radii of Mg^{2+} and Ba^{2+} .^[4]

Exchangeable cations are attracted to negative charges on the soil colloidal particles, forming an ion swarm in the diffuse double layer surrounding these particles. The specific adsorption increases with an increase in ion charge and with decreasing hydrated ion radius (because water

molecules act as an insulator). Exchangeable cations are present in the ratio $\text{Ca}^{2+} > \text{Mg}^{2+} > \text{K}^+ = \text{Na}^+$ in productive agricultural soils. Ca occupies the major part of the cation exchange complex in the neutral soils (e.g., up to 84% in Mollisols in Russia at pH 7.0) but also represents the most frequently occurring cation on the cation exchange complex in the acidic soils (e.g., 48% of the exchange complex in Lanna soil in Sweden).^[3] Only highly acidic, sodic, or serpentine soils may not have exchangeable Ca^{2+} as the dominant cation on the exchange complex; instead, they may be dominated by H^+ (acidic), Na^+ (sodic), and Mg^{2+} (serpentine soils).

Cation exchange capacity (CEC) refers to the sum of negative sites on soil solid phase that can bind cations and therefore protect them from being leached but keep them in a state that will allow replenishment of cations depleted from the soil solution. With increased soil acidity, there is a decrease in CEC.^[5] As a consequence, greater amounts of cations (especially basic cations like Ca^{2+} and Mg^{2+}) are present in soil solution and are therefore prone to leaching into deeper layers of the soil profile^[5] and eventually out of reach of roots. Liming of acidic soils results in an increase in effective CEC, with extra cation exchange sites mostly neutralized by Ca^{2+} .^[6]

Soil Solution Ca

An average Ca^{2+} concentration in the soil solution of temperate region soils is between 0.8 and 19.4 mM (30–730 mg/L),^[3,7] with the median values around 1.5 mM.^[8] Optimal growth of monocots, however, is already achieved at $<10 \mu\text{M}$ in flowing solution culture.^[9] Concentrations between 10 and 1000 μM of Ca are generally needed for optimal growth of dicotyledonous species.

The concentration of soil solution Ca^{2+} is regulated by the exchangeable Ca^{2+} , but the relationship varies for different soils. The ratio between exchangeable Ca^{2+} on the soil solid particles and Ca^{2+} in soil solution represents Ca buffer power; it ranges from 19 to 107 for various soils,^[10]

indicating a high capacity to replenish Ca^{2+} in soil solution.

Given the relatively high concentration of Ca^{2+} in the soil solution, the predominant transport pathway of Ca^{2+} toward roots is by mass flow rather than by diffusion. However, diffusion of Ca^{2+} toward roots occurs when uptake of Ca^{2+} is faster than the resupply by mass flow. In contrast, when mass flow exceeds uptake by roots, Ca^{2+} accumulates in the rhizosphere, creating a diffusion gradient away from roots. Most plants would take up less Ca^{2+} than the amount supplied via mass flow (e.g., ryegrass *Lolium rigidum*, subclover *Trifolium subterraneum*, and capeweed *Arctotheca calendula*), whereas some plant species can deplete Ca^{2+} in the rhizosphere by taking it up in excess of the supply by mass flow (e.g., lupin *Lupinus digitatus*).^[11] Therefore, the relative contribution of diffusion to Ca^{2+} transport toward roots depends on the plant's Ca requirement and on Ca^{2+} concentration in soil solution. If accumulation of Ca^{2+} takes place in the rhizosphere, precipitation of calcium carbonates or calcium sulfates may occur,^[10] especially in poorly leached, arid soils. Hence, soluble Ca^{2+} concentration in many arid soils is regulated not just by exchangeable Ca^{2+} but also by solubility of calcium sulfate and/or calcium carbonate.

Ca/Mg Ratio in Soil

Some authors have promoted the balance of soil exchangeable cations, particularly Ca^{2+} and Mg^{2+} , as an important criterion of soil fertility and productivity. The recommended range of the exchangeable Ca:Mg ratio in soil is 3–7.^[12] However, fertilization strategies based on cation saturation ratios (aimed at achieving a balance of soil cations instead of applying sufficient amounts of each nutrient) are not widely accepted.^[13] Although the concept has a good theoretical basis, it is undisputable that optimal plant growth may occur at a wide range of exchangeable Ca:Mg ratios (e.g., ratios ranging from 0.5 to 16 have produced constant yields for a variety of plant species and soil types).^[14,15]

Ca AS SOIL AMELIORANT

Amelioration of Acidic Soils

The widely accepted ameliorative measure for acid soils is liming, whereby Al held on the exchange complex is neutralized.^[16] Incorporating lime into the topsoil increases soil pH.^[3,4,16] In contrast, incorporation of lime into deeper horizons to ameliorate acidic subsoil is technically difficult and is frequently unprofitable.^[17] Alternatively, the surface-applied lime may in some cases allow sufficient leaching of Ca^{2+} down the profile to ameliorate subsoil acidity; this approach works well only in light-textured, sandy soils and requires lime rates sufficiently high not just

to neutralize topsoil acidity but also to provide surplus alkalinity to be leached into deeper horizons.^[16]

Lime reaction in soil is dependent on the nature and the fineness of the liming material. Dolomite [$\text{CaMg}(\text{CO}_3)_2$, with >15% Mg] has lower solubility but a higher surface area (smaller particle size) compared with calcite (CaCO_3); hence, the two types of material may have similar effectiveness in ameliorating acidic soil.

Amelioration of Sodic Soils

Sodic soils have high exchangeable Na^+ content and low hydraulic conductivity because Na promotes deflocculation and swelling of clay particles and thus dispersion of soils, especially those containing expanding montmorillonite clays.^[3,4] Amelioration of sodic soils hinges on replacing exchangeable Na^+ by Ca^{2+} and the restoration of a granular physical structure. For non-calcareous sodic soils, gypsum is the Ca-containing material of choice.

CA UPTAKE BY PLANTS

Ca deficiency in soils is rare and occurs only on serpentine soils derived from Mg-rich materials or on highly leached acidic Al-saturated soils. Even under those conditions, Ca deficiency in plants may be owing to Mg- or Al-repressing Ca uptake rather than owing to absolute Ca deficiency.

Symptoms of Ca deficiency are leaf distortion and petiole collapse (e.g., in *Glycine max*), rolled young leaves (e.g., in small grains), collapsed midrib, terminal dieback and defoliation (e.g., in *Prunus persica* seedlings), or reduced rate of wood formation and decreased amount of functional sapwood and live crown.^[18]

An average Ca concentration in the plant material is around 5 g/kg dry weight, which is about 125,000 times greater than for molybdenum as the least abundant nutrient and about 1/8 of nitrogen as the most abundant nutrient in plant tissue. Greater tissue concentrations of Ca are required in dicot compared to monocot plants.^[19] Most of Ca is bound in the cell wall (about 60%) or sequestered in different organelles.^[20] The activity of free cytosolic Ca^{2+} is therefore very low (10^{-7} to 10^{-6} M),^[21] preventing reaction of Ca^{2+} with inorganic phosphates and thus Ca^{2+} cytotoxicity.

Plant roots have CEC similarly to soils.^[22] Therefore, one cation exchanger (root) is in contact with the other (soil), resulting in competition for cations based on physicochemical principles. Plant capacity to take up cations is at least partly influenced by the root CEC^[23] because ionic environment at the plasma membrane surface (where uptake of all ions takes place) depends on the strength of the electrical field developed in interaction of two charged surfaces (root and soil particles).

Ca uptake is via an apoplastic pathway and is thus hindered by the Casparian strip or any suberization in the root

cell walls in general. Therefore, the most effective transport of Ca^{2+} is at the root tip.^[24,25] Transport of Ca^{2+} across the root cell plasma membrane into the cytosol is down the concentration gradient (high in the apoplast and low in the cytosol) via Ca^{2+} -selective channels.^[25,26]

Ca is transported mainly in the xylem sap, whereas its mobility in the phloem sap is poor. As a consequence, concentration of Ca is greater in mature and old leaves than in the young ones.^[27] Similarly, transport of Ca into fruits and grain is poor. The typical example of inadequate supply of Ca to developing fruits is blossom-end rot in capsicum and tomatoes^[28] and bitter pits in apples and pears.^[29]

Ca content in soils determines distribution of plant species in the natural ecosystems. Calcicole species are adapted to soils rich in Ca (these species are also sensitive to Al). In contrast, calcifuge species have a low Ca demand and are therefore adapted to acid, low-Ca soils (these species are also tolerant to Al).^[8,18]

CONCLUSION

As the predominant soil exchangeable cation, Ca^{2+} determines chemical and physical properties of soil. Ca can easily be leached into deep soil layers, causing topsoils to acidify. Ca lost by leaching and by export in farming products should be replenished. Liming is used to restore Ca content as well as to neutralize acidity.

Abstract

Diffuse reflectance spectroscopy based on near-infrared radiation [near-infrared reflectance spectroscopy (NIRS)] has become an important method for analyzing agricultural products, where large numbers of measurements are needed to detect variations in product composition that impact market value (i.e., protein in grains and food/feed composition) or to monitor and measure spatial and temporal variation in environmental parameters (i.e., soil carbon and other soil properties). Diffuse reflectance spectroscopy, using Fourier transform mid-infrared [diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS)], has also been shown to be capable of rapid quantitative analysis of agricultural products and environmental samples. Through a process termed “chemometrics,” information contained in the entire spectrum is related to the property of interest by the use of multivariate statistical techniques such as stepwise regression, principle component analysis, or partial squares least regression. Mathematical models produced by these techniques form the calibration models that are used to predict properties of unknown samples. With the development of robust calibrations, NIRS and DRIFTS have the ability to analyze samples rapidly and simultaneously for multiple properties with virtually no consumables and minimal sample preparation.

QUANTITATIVE ANALYSIS BY DIFFUSE REFLECTANCE

Basics on Diffuse Reflectance

From a historical perspective, the analytical use of spectroscopy has often involved measurement of light transmission through a sample held in, e.g., a cuvette, such as in colorimetric determinations, or through a sample squeezed between salt plates in the case of mid-infrared (mid-IR) spectroscopy. Over the last decades, a quantitative analytical approach has been developed based on a process called diffuse reflectance (Fig. 1), and this approach has come to dominate the analysis of many agriculture products.^[1] In this method, samples can be scanned in an open sample cup (sealed cups are used for some instrument configurations depending on the spectral range) with the surface prepared by either scrapping across the surface of the cup with a straight edge or smoothing in a similar manner with a spatula.

Examination of Fig. 1 reveals that light radiation hitting a particulate sample in a cell can interact in several ways. Light directly reflects off either the cell window (A) or sample (B) undergoing specular (mirror-like) reflection which provides no compositional information. This is also

true for light that enters but never leaves the sample (D). However, light, which penetrates sample particles and is then reflected back to be collected by some detector arrangement, (C) is said to be diffusely reflected and provides compositional information based on the absorption pattern.

Most of this work has been performed using radiation in the near-infrared (NIR) spectral range, 9000–4000 cm^{−1}, because of the belief that spectral distortions caused by specular reflection in the mid-IR^[2] made quantitative analysis, using Diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS), impossible despite the greater wealth of spectral information present. However, it has been demonstrated that despite the spectral distortions present in DRIFTS spectra, quantitative analysis can be performed^[3–8] with an accuracy often greater than that achieved using near-infrared reflectance spectroscopy (NIRS).^[7–9]

Chemometrics

Unlike quantitative analysis using colorimetry, where only one or two absorbing components are changing at any given time and thus only one or two wavelengths need to be monitored, quantitative analysis using spectra such as

Fig. 1 Diffuse reflectance for a ground sample. (A) Reflection of cell window, (B) specular reflection of sample surface, (C) diffuse reflection giving rise to spectral information, (D) total absorption.

those shown in Fig. 2 requires many spectra with a range of values for the analyte in question, because many components are absorbed at the same spectral locations and the concentrations of many components are simultaneously changing from one sample to the next. The process of developing and testing calibrations using multivariate statistics for quantitative analysis has come to be known as chemometrics.^[1,10] The statistical methods used are said to be multivariate in nature, in that many wavelengths (stepwise regression) or even all (i.e., principle component analysis, partial least squares analysis, and neural nets) are used to relate the analyte information to the spectral data. Because of the many spectral values often available (100–1000s of values per spectrum), it is also very easy to produce spurious correlations if only a few 10s of samples are used. This is called overfitting, and the resulting equation is useless for predicting new samples. The use of too few samples for calibration development is also probably the biggest error made by novice users of chemometric techniques.

Simultaneous Determination of Multiple Analytes

Spectral information is a characteristic of the sample and does not change with the analyte of interest, only the

Fig. 2 Near-infrared spectra (A) of low C (I) and high C (II) and mid-infrared spectra (B) of high C (III) and low C (IV) soil samples (approximately 0.1 and 3% organic C contents).

specific spectral data needed for calibration changes with the analyte of interest, i.e., different absorptions relate to carbon (C) as opposed to nitrogen (N), etc. Thus, once a spectrum is obtained, the same spectrum can be used to determine different analytes, assuming calibration equations are available, i.e., one or a hundred analytes can be determined in a matter of moments from the same spectrum. Thus, NIRS and DRIFTS can greatly reduce the time for sample analysis when many samples and analytes per sample are going to be determined.

Potential for Soil Analysis

The chemometric approach using NIRS and DRIFTS works best when large numbers of samples are involved both from the standpoint of the need to avoid overfitting and from the point of being worth the time to develop the calibrations. Because of the possibility of using C sequestration in soil as a means to remove carbon dioxide from the atmosphere, there is increased interest in detecting changes in the amounts of C present in soil. Because of differences in the lability of various forms of soil C, there is also interest in determining differences in the composition of the C present. The “gold standard” for the determination of total, organic, and inorganic C in soils is combustion that requires two runs to determine both organic and inorganic C (in the form of carbonates) and cannot distinguish forms of C such as charcoal different from other forms of organic C. As a result, it cannot determine labile as opposed to non-labile organic C, unless extractions are performed and the C content of the extracts determined. NIRS and DRIFTS offer the possibility of determining the forms of organic C present while simultaneously determining the organic C vs. inorganic C and do so at a greatly reduced cost and speed many times the conventional methods. Similarly, the advent of data-intensive technologies such as site-specific agriculture has generated the need for large databases, and the analysis of large numbers of samples so that spatial structure in agricultural fields can be characterized.

Soil Calibration Example

In Table 1, results are presented from a set of 237 soils collected over a wide range of the Western United States.^[8] These samples were available in acidified (carbonates removed) and non-acidified forms. Calibrations were developed using three-fourths of the samples and then used to determine the remaining one-fourth. As demonstrated, results using DRIFTS were much better than the corresponding NIR results, with results overall very similar to those found for the calibration set. These results support the conclusion that a

Table 1 PLS results using three-fourths of samples to develop calibration and remaining one-fourth as an independent test set.

Assay	Calibration results		Test results		Bias ^a	RD ^b
	R ²	RMSD	R ²	RMSD		
Mid-infrared spectra ^c						
Organic C ^d	0.985	1.62	0.967	2.42	0.552	18.0
Organic C ^e	0.949	3.03	0.942	3.15	0.016	23.4
Inorganic C ^e	0.991	1.11	0.983	1.20	0.328	22.6
Total C ^e	0.967	2.89	0.946	3.42	0.381	18.2
Near-infrared spectra ^c						
Organic C ^d	0.829	5.54	0.800	5.77	−1.11	42.8
Organic C ^e	0.844	5.28	0.822	5.47	0.084	40.6
Inorganic C ^e	0.968	2.03	0.872	3.14	−0.141	59.2
Total C ^e	0.873	5.71	0.861	5.41	−0.321	28.8

Note: RMSD = root mean squared deviation (%).

^aActual – predicted mean value.

^bRMSD/Mean as percent.

^cSpectral ranges for mid- and near-infrared, 4000–10,000 and 10,000–400 wavenumbers, respectively.

^dAcidified samples to remove carbonates.

^eNon-acidified samples.

DRIFTS calibration could be developed using these samples, which could be used to determine the C values for other samples from the same geographical locations, thus greatly reducing the need for combustion analysis.

CONCLUSION

Results from a variety of data sets have demonstrated that NIRS and DRIFTS show great potential for the determination of soil composition, especially soil C. While mid-IR calibrations for soil C appear to be more accurate and robust, the use of DRIFTS for quantitative analysis is not nearly as developed as that of NIRS and may be more difficult to make portable. With reasonable input of resources, spectroscopy has the potential to generate the extensive databases on soil properties needed for producing spatial structure maps for soil properties that can then be used for site-specific management of agricultural lands. Results have also shown that accurate calibrations can be developed using NIR or mid-IR spectra for the determination of a number of compositional parameters including total C, total N, pH, and many measures of biological activity as reflected by enzyme activities and measures of biologically active N. While efforts at determining the robustness of mid-IR calibrations indicated that mid-IR soil calibrations generally performed in a manner similar to NIR calibrations, differences found indicate that the basis for mid-IR calibrations may at times be different.

Abstract

The carbon (C) accretion rate in different aquaculture ponds ranges from 0.28 to 4.37 Mg/ha/yr with an average of 1.56 Mg/ha/yr. The culture of tilapia and carp has a high C accretion rate while freshwater prawn may have a low rate. Aquaculture ponds could sequester 17.2 Tg/yr of C from 11.1 million hectares (Mha) of aquaculture ponds globally.

INTRODUCTION

With the increase of atmospheric carbon dioxide (CO₂) concentration, considerable attention has been devoted to terrestrial carbon (C) storage in soils, forests, and grasslands. The depositional environments (i.e., lakes and impoundments) represent short- to long-term scale storage of atmospheric CO₂. Globally, this storage of organic C (OC) in the sediments of natural lakes ranges from 30 to 70 Tg C/yr (Tg = teragram = 10¹² g = 1 million metric ton).^[1–3] The burial in impoundments is much larger ranging from 150 to 220 Tg C/yr.^[4] These rates of C burials are comparable to the OC storage in the sediments of the global oceans estimated at 120–240 Tg C/yr.^[5–7] The annual magnitude of OC stored in lakes and reservoirs is also comparable to the delivery of OC by rivers to the ocean, about 400 Tg C/yr.^[8–10] However, these rates of OC storage in lakes and agricultural impoundments are modest compared to the total storage of OC terrestrially that ranges from 1000 to 4000 Tg C/yr.^[11] Wetlands also accumulate significant amounts of C in their soils, compared to adjacent upland sites.^[12] Strategies to reduce C and other greenhouse gas emissions from agriculture and enhance C sinks on farms/wetlands have also been identified,^[13–16] but options for different aquaculture farming systems have not been widely assessed.

There are 11.1 million hectares (Mha) of aquaculture ponds globally.^[17] Manures, fertilizers, feed, and other agricultural wastes are applied to ponds for higher production, and these inputs stimulate OC production by phytoplankton photosynthesis in ponds.^[18] Aquaculture ponds do not have large external sediment loads like

reservoirs or watershed ponds in agricultural or other rural areas. Further, sediments in aquaculture ponds are eroded by rain, waves, and water currents generated by mechanical aerators, activities of different culture species, and harvesting operations. Thus, coarse soil particles suspended by internal erosion settle near the edge of ponds while smaller particles tend to settle in deeper areas of the ponds.^[19] Uneaten feed, organic fertilizers, organic matter (OM) from dead plankton, and excreta from different species settle at pond bottoms and gradually mix with soil particles. When ponds are drained for harvest, organic detritus is discharged from the ponds, and after draining, pond bottoms are exposed to sunlight for drying that enhance soil aeration and accelerate decomposition of labile OM.^[20] Despite these practices in aquaculture ponds, a layer of sediments with a higher OC concentration than that in the original soil develops at the pond bottom.^[21] Aquaculture ponds store as much as 0.21% of the annual global C emissions of about 10 Pg/yr and represent a small sink for C that is an important ancillary benefit in considerations of the global C budget.^[22] However, detailed data on C storage by aquaculture ponds are scanty globally. Thus, this entry will be dealt with the potentialities of the soil C sequestration in fish ponds.

MATERIALS AND METHODS

Inputs in Aquaculture Activities

Aquaculture activities involve a variety of inputs for fish production including manures, fertilizers, feed, and a

combination of all these things. In addition to this, lime is applied, if necessary. With high fertilization rate, the nutrients assimilated in fish biomass were estimated to be less than 20–30% for nitrogen (N), 10–15% for phosphorus (P), 10–20% for OC.^[23,24] Most of those lost nutrients are distributed in water, fish biomass, and sediments of the pond systems. It is generally believed that a large proportion of nutrients received in ponds end up in pond muds and discharged effluents.^[25] The organic fertilizer (cow dung) contained 40–42% C (on dry weight basis), while feed contained 46–48% C (on dry weight basis). The carps, freshwater prawn (scampi), shrimp, and tilapia contained 11.0–13.5% C (on live weight basis).^[26]

Sediment Core Analysis

The average depths of fish ponds vary between 1.0 and 2.5 m. Sediment cores could be collected manually from the ponds.^[27] Sediment accumulation rate could be estimated by dividing the sediment depth by the age of the pond. Wet sediment samples could be weighed, a measured quantity dried for 24 hours at 105°C, cooled in desiccators, and weighed again for dry bulk density estimation. A part of sediment samples were air-dried, pulverized to pass a 0.25-mm screen, and could be analyzed for OC using dichromate oxidation technique by rapid titration method. The OC accretion rate could be estimated by multiplying the annual rate of accumulation of dry sediment by the sediment dry bulk density and the

OC concentration in the sediment. The soil OC accretion could be computed using the following equation:^[13]

$$\text{Mg C/ha} = (\%C \times \text{corrected bulk density} \times d \times 104 \text{ m}^2/\text{ha})/100$$

where Mg C/ha represents mega gram of C per hectare (1 Mg = 10⁶ g = 1 metric ton), soil bulk density is represented in mega gram per cubic meter, and d is the depth measured in meters.

RESULTS AND DISCUSSION

Rate of Sediment Accumulation

The rate of sediment accumulation ranged from 0.9 to 1.20 cm/yr in shrimp ponds, 1.10 to 1.54 cm/yr in freshwater prawn ponds, 1.10 to 2.33 cm/yr in tilapia ponds, 188 cm/yr in polyculture ponds, 1.00 to 3.70 cm/yr in carp ponds, 1.20 cm/yr in channel catfish ponds, 2.50 cm/yr in Clarias catfish ponds, 0.45 cm/yr in yellow perch ponds, and 0.80 cm/yr in bait minnow ponds, respectively (Table 1). Overall, the sediment rate accumulation ranged from 0.45 to 3.70 cm/yr in these ponds. When ponds are drained, considerable amount of sediments are lost from the bottom of the ponds through outflow or runoff. Ponds are usually drained once in every 3 years till the upper layer cracks to reduce the concentration of toxic gases in the pond bottom. The dry bulk density (g/cm³) of sediment in these ponds ranged from 0.49 to 0.63 in shrimp, 0.18 to 0.46 in prawn,

Table 1 C accretion from the data of sediment core analysis for different aquaculture systems.

Species	Country	Sediment accumulation (cm/yr)	Sediment dry bulk density (g/cm ³)	OC (%)	C sequestration (Mg/ha/yr)	References
Shrimp	Honduras	0.90	0.50	2.10	0.95	[22]
	India	1.62	0.49	1.22	0.97	[26]
	Thailand	1.20	0.63	3.66	2.76	[28]
Freshwater prawn	India	1.54	0.46	1.20	0.86	[26]
	Thailand	1.10	0.18	1.38	0.28	[29]
Tilapia	Brazil	1.25	0.51	4.17	2.65	[22]
	South Africa	2.33	0.56	3.35	4.37	[22]
	Thailand	1.10	0.35	3.00	1.15	[30]
India major carps with prawn (polyculture)	India	1.88	0.58	1.37	1.43	[26]
Carps	India	1.00	1.10	1.10	1.21	Unpublished
	Thailand	3.70	0.28	3.02	3.12	[29]
Channel catfish	Alabama, U.S.A.	1.20	0.38	2.92	1.33	[22]
Clarias catfish	Thailand	2.50	0.18	1.46	0.66	[29]
Yellow perch	Piketon, U.S.A.	0.45	0.84	2.80	1.06	[31]
Bait minnow	Arkansas, U.S.A.	0.80	0.47	1.58	0.59	[32]

0.34 to 0.56 in tilapia, 0.58 in polyculture, 0.28 to 1.10 in carps, 0.38 in channel catfish, 0.18 in Clarias catfish, 0.84 in yellow perch, and 0.47 in bait minnow ponds (Table 1). Overall, the bulk density of soils of these ponds ranged from 0.18 to 1.10 g/cm³.

OC Concentration in Sediment

The OC concentration (% g/g) in sediment ranged from 1.22 to 3.66 in shrimp, 1.20 to 1.38 in freshwater prawn, 3.00 to 4.17 in tilapia, 1.37 in polyculture, 1.10 to 3.02 in carps, 2.92 in channel catfish, 1.46 in Clarias catfish, 2.80 in yellow perch, and 1.58 in bait minnow ponds (Table 1). Overall, the OC in sediment varied from 1.10% to 4.17% in different ponds of the world. There were no clear trends in OC concentration related to culture species or intensity of culture. Significant quantities of OM can accumulate in bottom sediments in these aquaculture ponds. Feeds applied to these ponds to increase fish/prawn/shrimp settle at the bottom where it is mostly eaten by aquatic species. Inorganic nutrients released into the water from microbial decomposition of uneaten feed and feces of these species stimulate heavy plankton blooms. Phytoplankton cells have a short life span and continually die and settle to the bottom. In some cases, water supplies contain solids of appreciable OM content that may deposit in ponds. High rates of water exchange may result in large sediment inputs. Mechanical erosion may often erode bottom particles where water currents are higher and sedimentation occurs where currents are slower. Such a current flow pattern alters the shape of the bottom of the pond, reduces pond volume, and provides organic substrate for microorganisms.^[33]

Rate of C Sequestration

The annual C accretion rate estimated from sediment accumulation rate, dry bulk density, and percentage OC in sediment ranged from 0.95 to 2.76 Mg/ha/yr in shrimp ponds, 0.28 to 0.86 Mg/ha/yr in prawn ponds, 1.15 to 4.37 Mg/ha/yr in tilapia ponds, 1.43 Mg/ha/yr in

polyculture ponds, 1.21 to 3.12 Mg/ha/yr in carp ponds, 1.33 Mg/ha/yr in channel catfish ponds, 0.66 Mg/ha/yr in Clarias catfish ponds, 1.06 Mg/ha/yr in yellow perch ponds, and 0.59 Mg/ha/yr in bait minnow ponds (Table 1). Overall, the C sequestration rate in these ponds ranged from 0.28 to 4.37 Mg/ha/yr with an average of 1.56 Mg/ha/yr. The culture of tilapia and carps recorded the highest C storage while freshwater prawn recorded the lowest. The freshwater prawn prefers clear bottom (sandy) for their growth. In general, tilapia and carp stir pond sediment in search of food organisms, and this action possibly incorporates deposited OM into sediment to minimize its loss during pond drainage for harvest.^[22]

The applied nutrients from different sources in the culture systems and also the nutrients entering from the terrestrial into aquatic ecosystems through runoff have an important role in C sequestration by the sediment in fish ponds. Fertilizers and feeds are generally the largest inputs of N and P to fish ponds. Feeds also supply C to fish ponds. Organic fertilizers (fermented rice straw, cow dung, etc.) are often added to ponds to boost fish yields by increasing primary productivity through released inorganic nutrients or by providing OC through heterotrophic pathways. Depending on the species, fish feed directly on attached or planktonic algae, detritus/fungal flocs, or smaller animals such as zooplankton and snails that feed on algae and detritus.^[34] Ponds also receive nutrients from the regulated inflow water.

The estimated average annual C sequestration rate for aquaculture ponds monitored in this study is lower than that of agricultural impoundments and large river reservoirs but higher than that of natural lakes and inland seas (Table 2). Aquaculture ponds can sequester 17.2 Tg/yr of C globally. Aquaculture ponds store less C than that by large reservoirs (160–280 Tg/yr^[1,37]) and agricultural impoundments (163 Tg/yr^[36]). The aquaculture ponds store C at a lower rate than agricultural impoundments and large reservoirs because of lower input of external sediment and associated OM to aquaculture ponds than in other impoundments.^[22] Moreover, aquaculture pond management minimizes OM accumulation.

Table 2 Areas of global inland water bodies and annual rates and amounts of OC storage in these systems.

Inland water body	Global area (Mha)	C sequestration rate (Mg/ha/yr)	Global C storage (Tg/yr)	References
Aquaculture ponds				
Freshwater	8.75	1.56	13.6	[35]
Brackish water	2.33	1.56	3.6	[35]
Large lakes	118	0.05	6.0	[1]
Small lakes	32	0.72	23.0	[1]
Inland seas	100	0.05	5.0	[1]
Large river reservoirs	40	4.00	160	[1]
Agricultural impoundments	7.7	21.20	163	[36]

For example, ponds are dried at least once in 3 years to reduce the gaseous emissions from the bottom and also to flush out sediments using pressurized water. This intervention is needed because a thick layer of the sediment reduces the productivity of the pond. Although aquaculture ponds sequester comparatively small amount of C, globally pond farming systems under different management practices can sequester a large amount over long term.

Carbon Sequestration: Geologic

Eswaran Padmanabhan

Geoscience, University Teknologi Petronas, Bandar Seri Iskandar, Malaysia

Abstract

Carbon (C) has been sequestered naturally in soils and geological formations. The efficiency of the sequestration in soils depends on several factors. There are several challenges to maintaining the C pool in soils. Overall, C sequestration in soils can be hampered by mismanagement. Geological sequestration of carbon dioxide can be done in a few ways as well. However, high costs and the need for monitoring for possible leakage appear to be some of the major concerns regarding this type of sequestration. In comparison with soil sequestration that happens mostly in a natural manner, geological sequestration is anthropogenic in nature, involves high costs, and has a risk factor associated with it since the integrity of the containment will always be of our main concern. Nevertheless, as anthropogenically produced C is very high and is expected to be much higher, technology is driven to excel in the field of sequestration for long terms. The success of this technology can only be accessed with time.

INTRODUCTION

Carbon (C) has been sequestered naturally in the various components such as geological formations, soil, oceans, and wetlands. The three major pools of C are ocean, terrestrial, and atmosphere. The oceans contribute approximately 39,000 Pg (10^{15} g) of C, the terrestrial system about 2500 Pg, and the atmosphere about 750 Pg. The various estimates for C pool in soils range from 1220 Pg to 1576 Pg. Human activities are believed to have changed the atmospheric composition, including increasing the atmospheric carbon dioxide (CO_2) concentration, leading to global warming. Crowley,^[1] Karl and Trenberth,^[2] Manabe and Stouffer,^[3] Johns et al.,^[4] and Cox et al.^[5] pointed out that the terrestrial biosphere has lost the ability to act as a C sink as temperature rises. It is beyond the scope of this entry to discuss the reasons as to why the terrestrial biosphere has lost the ability to act as a C sink. However, the reader is referred to entries on soil degradation in this encyclopedia for further information on this subject matter. Many authors have indicated that reducing the impact of CO_2 emissions on the atmosphere and, therefore, global climate change would be a challenging task.^[6–11]

Soil C sequestration specifically deals with the transfer of CO_2 from the atmosphere into the soil via crop residues and other organic solids in a form that is not easily released back into the atmosphere. The rates of accumulation of C in soils are also known to be different.

Oil and gas companies have been injecting CO_2 in geological formations for many years. Traditionally, the CO_2 that is produced from anthropogenic factors is released to the atmosphere. In order for this type of sequestration to

reduce global emissions of CO_2 to preindustrial levels, the volume involved in the process must be huge.

Geological storage is achieved by injecting CO_2 into porous rock formations.^[12–14] Reservoirs that can be used for geological storage of CO_2 include sedimentary basins, depleted oil reservoirs, and non-economic coal beds. The stability of the impermeable caprock is important in such storage projects since a breach in the cap will release the buoyancy-driven, upward-migrating CO_2 into surrounding marine waters and eventually back into the atmosphere. It has been stated that caprocks are the primary seal during the life cycle of the CO_2 geological storage in a reservoir.^[15,16]

In essence, geological sequestration implies injecting CO_2 at depths of about 1–2 km, whereas sequestration of CO_2 in soils occurs in the solum. The rate of sequestration in soils tends to vary based on several factors such as soil type, temperature, organic C pool, pedological conditions, and humidity. In contrast, the ability to sequester CO_2 in geological strata depends on factors such as permeability, porosity, pore throat size, resident pressure, temperature at depth of sequestration, and mineral stability as well as other conditions that influence solid–liquid interactions. It is evident from the preceding discussion that CO_2 can be sequestered differently in different media. This entry discusses these basic differences and highlights the need to conserve and sustain the natural resources in order to better manage the increasing CO_2 contents on a global basis.

DEFINITIONS

It is well known that the produced CO_2 needs to be prevented from entering the earth's atmosphere for a

period of time sufficient to allow climate stabilization. Unfortunately, the optimum period of time that is required for this stabilization is not well understood. Generally, it is believed that the optimum period would be hundreds, if not thousands of years. As such, there is a need to store, in a safe manner, the produced CO₂ for extended periods of time.

The terms storage and sequestration have been occasionally used interchangeably and therefore merit a proper distinction. Mere physical storage would not seem to meet the stringent requirements of being able to hold back the stored CO₂ from entering the earth's atmosphere for thousands of years. Therefore, the storage mechanism is required to incorporate a chemical fixation of the CO₂ in a manner that the release would not occur easily and that too for a long time. This then provides the basic difference between CO₂ storage and CO₂ sequestration, the latter being the preferred long-term isolation of produced CO₂.

Essentially, sequestration means the transfer of atmospheric CO₂ into a form that has a high mean residence time that is long enough so that the CO₂ is not reemitted into the atmosphere. There are three types of C sequestration:^[17] 1) those that involve photosynthesis of plants that convert atmospheric CO₂ into biomass, soil organic matter, and other components; 2) those that involve engineering techniques; and 3) those that involve chemical transformations.

Another term used in this entry is EOR. EOR stands for enhanced oil recovery. Basically, this refers to the recovery of oil that is not easily recoverable. In such cases, additional effort is needed to expel the oil from the reservoir. Several methods are used in EOR endeavors. They include gas flooding and water-alternating gas or the use of surfactants. Chemical flooding is another EOR technique used (this includes, e.g., rock-fluid chemical reactions, application of new chemicals). Lastly, thermal methods and unconventional methods such as application of solvents and chemicals to steam flooding, modelling, and simulation are used in some cases as enhanced recovery techniques.

C SEQUESTRATION IN THE PEDOSPHERE

The natural processes of sequestering are generally cost-effective and tend to enhance the quality of the ecosystem.^[18] Sequestration in terrestrial systems is high in protected areas as well as in well-managed agricultural systems. Factors such as soil types, vegetation, and climatic conditions also play an important role in the rate of sequestration. Sustainable management of wetlands ensures optimum natural sequestration in aquatic ecosystems.

The bulk of the CO₂ emitted into the atmosphere is sequestered naturally in terrestrial ecosystems. Lal^[19]

estimated that about 25% of the amount of C released into the atmosphere by human activities is sequestered in soil organic matter on an annual basis. Plants play an active role in sequestration in terrestrial and wetlands, and therefore, it is not surprising to note that organic C is added to the soil regularly by plants and animals as well as from agricultural practices.

Soils with degraded organic C pool represent a unique challenge to scientists as the ability of the soil to function in a normal capacity to sequester C is impaired. In the first instance, issues such as erosion, acidification, nutrient mining, degradation of soil structure, and even contamination from excessive use of fertilizers or pesticides, herbicides, and other chemicals require continuous and intensive attention in order to keep the soil quality within the resilience capacity. The tropics host about 750 million hectares of degraded lands.^[20] The capacity of soils to sequester C depends on our ability to restore the soil to the original status.

There are numerous challenges that need to be overcome in order to enhance the C storage capacity of soils. The soil organic carbon (SOC) pool has to be improved especially in agricultural soils since these lands make up a huge proportion of our land space. Humification is a process of converting biomass C into stable humic substances, thereby improving the storage capacity of C in soils. Unfortunately, this process is very complicated and requires extensive research in order to implement or even improve this in degraded lands.

Another associated challenge in trying to enhance the C storage capacity is in intensifying the organo-mineral complexes especially in degraded soils. Organo-mineral complexes are by their very own nature very complicated in terms of their structure, bonds, and chemical tendencies. In addition to this, the sequestering capacity of soils can be altered simply by changing the type of land use. This basically means that a good cost-benefit analysis needs to be done in every farming system in order to assess the values in improving the C balance in such systems.

It has been mentioned that a combination of nanotechnology and biotechnology is very useful in the restoration of degraded soils and associated ecosystems, thereby enhancing the soil organic matter pool. The techniques range from the use of nanoporous materials, use of genetically modified organisms, and bioremediation of degraded lands. The very act of restoring degraded lands gives many benefits such as increased available water-holding capacity, elevated nutrient retention capacity, increased water infiltration capacity, and also increased C sequestration. More research needs to be done in this area, as the type of degraded lands present, especially in the tropics, is large and each represents a unique problem. It has been estimated that the gross rate of SOC sequestration ranges from 500 to 800 kg/ha/year in cold and humid regions and 100 to 300 kg/ha/year in dry and

warm regions in the Midwestern region of the United States.^[21] Such differences have to be taken into account when remediation techniques are implemented. The reader is referred to other parts of the encyclopedia for further information on soil remediation.

Despite knowing that soils and the rest of the terrestrial system can sequester huge amounts of C, it is very important to recognize that the C pool in soils can be easily destroyed by mismanagement of the land. The reader is referred to other sections of this encyclopedia for further information on this subject.

GEOLOGIC C SEQUESTRATION

Oldenburg^[22] has shown that the physical state of CO₂ is dependent on temperature and pressure. At room pressure and temperature, CO₂ is in a gaseous state. At greater depths, the gas can become a liquid and even reach a supercritical state at very high pressures. As such, CO₂ is usually injected in a liquid form, but the material transforms into other states as explained, when it moves into the sedimentary formation at various confining pressures and temperatures.

Large sedimentary basins are best suited for CO₂ sequestration mainly because of the large pore volume and connectivity.^[23] This is essential to maximize the amount of gas that can be injected into the formation. A suitable formation is more than 800 m deep, has thick and extensive seal, sufficient porosity, and permeability to allow large volume of gas injection at high flow rates without requiring high pressures.^[14] The need to reduce the pressure of injection is critical so as not to breach the seal for the formation.

There are about five ways to sequester CO₂ in geological media (Fig. 1). First, the CO₂ can be utilized in EOR operations to displace hydrocarbon and be sequestered at the same time. The CO₂ can be disposed of in disused oil and gas reservoirs or used to displace methane in coal

beds. The CO₂ can also be injected in deep saline aquifers and/or be stored in salt caverns.

There are various estimates for the capacity to sequester CO₂ by these different methods. According to Intergovernmental Panel on Climate Change,^[24] depleted oil and gas reservoirs have the capacity to sequester an estimated 675–900 Gt C. Saline aquifers have been estimated to be able to sequester about 1000–10,000 Gt C, whereas deep and unminable coal beds have the lowest potential to sequester (3–300 Gt C). Mineral carbonation involves the transformation of industrial CO₂ into calcium carbonate, magnesium carbonate, or other stable carbonate minerals. Basalt aquifers occur in many oceans and could sequester 2.3–11.5 Tt-C along seismic ridges and 5.9–29.6 Tt-C along aseismic ridges.^[25] Although these estimates vary from place to place, it is to be noted that the conditions within and external to the formation are not the same globally. Therefore, the actual sequestration capacity becomes a function of locality and time.

CO₂ is a reactive gas and as such can interact with both the rock and formation fluids in injected reservoirs. A number of studies have attempted to predict the behavior of CO₂ under a range of physical and chemical conditions.^[26,27] It is interesting to note that CO₂ solubility depends on temperature, pressure, and composition of formation fluids.

The rate of injection, surface area of CO₂–water interaction, and the degree of mixing control the proportion of injected volume that dissolves. Dissolution of this CO₂ results in mineral dissolution and precipitation.^[28] The precipitation of C-bearing minerals provides a long-term sequestration of CO₂. Studies show that about 1% of the CO₂ precipitated as carbonate minerals, the dissolved phase was 15–20 times more than that, and the rest stayed as an immiscible phase.

Apart from these factors, pressure and hydrodynamic and geothermal regimes in a basin have a significant impact on its potential for CO₂ storage. It is well known that fluids and gases do not remain stationary in the subsurface but migrate at rates related to their composition, state, and the resident pressures in the basin.

The geological fill of a basin and the internal heterogeneities at all scales, including faults and fractures, depositional patterns, and porosity–permeability trends, affect the capacity and effectiveness of CO₂ storage. The buoyancy-driven migration of immiscible CO₂ is controlled by barriers and increases the CO₂–water–rock interaction. This internal heterogeneity can also have a negative impact on storage effectiveness. It has outlined that four trapping mechanisms that can contribute to the long-term retention, i.e., structural, capillary, solubility, and mineral trapping.^[24] The reader is encouraged to review this document to gain further insight on these mechanisms.

In the actual sequestration process, engineering techniques^[7,29,30] used include injecting compressed and

Fig. 1 The various types of geological carbon sequestration. A. CO₂ in enhanced coal bed methane recovery. B. CO₂ in EOR projects. C. Injection into deep saline formations D. Sequestration in depleted oil and gas reservoirs.

liquefied CO₂ beneath the ocean, into sedimentary formations, abandoned hydrocarbon reservoirs, saline aquifers, and brown fields as an EOR technique and to displace coal bed methane in unminable coal seams.^[31,32] The main concerns with geologic sequestration revolve around high costs^[18] and CO₂ leakage. Despite technological advancements, the concerns regarding breach of the seals due to abnormal pressures, reactivation of fissures and fractures, and seepage through old and new fissures require new protocols to be continually developed and tested for the measurement, monitoring, and verification. The issue of stability of the caprock seals is beyond the scope of this entry.

CONCLUSION

This entry discusses the sequestration potential of geological formation as opposed to soils. It is evident from the foregoing discussion that the success of the various methods can only be assessed with time. This is simply because there is some uncertainty on the long-term stability of the solid–gas interface phases. Large sedimentary basins can only be available for sequestration when the field is declared as a brown field or when EOR methods have been decided to be implemented in the said field. In addition to this, a good understanding of the reservoir properties is essential in ensuring a success in the sequestration procedure.

In a similar argument, maintaining the stability of the organomineral complexes in soils under various types of land management is a challenge. The basic idea of sequestration lies in the ability of the system to retain the gas for a long period of time. As such, an additional challenge would be to increase the retention rates to achieve this target.

It is therefore concluded that the naturally sequestered CO₂ in soils needs to be safeguarded in as much as the ability of the soils to continue to sequester the same gas. Geological sequestration of CO₂ raises several questions with regard to the level of technology that needs to be used in order to ensure long-term stability and sequestration of the gas.

Carbon Sequestration: Iceland

Anna María Ágústsdóttir

Soil Conservation Service, Hella, Iceland

Abstract

Mitigation of human-induced changes to the climate of the earth is among the most pressing environmental challenges. Reducing emissions of greenhouse gases (GHGs) and returning some of the carbon (C) back to earth are both essential tools if countries are to become C neutral with regard to the greenhouse effects. Terrestrial C sequestration involves capturing the atmospheric C through photosynthesis and subsequently storing them in soils, wetlands, and biota. Being C neutral refers to reducing national GHG emissions as far as possible and offsetting the remaining emissions by reduction elsewhere.

INTRODUCTION

The concept of carbon (C) neutrality is fairly new and refers to reducing national greenhouse gas (GHG) emissions as far as possible and offsetting the remaining emissions by reduction elsewhere (Fig. 1). It is a voluntary action taken by countries, companies, or individuals without legal requirements, setting emission reduction targets well beyond targets set by international agreements such as the United Nations Framework Convention on Climate Change (UNFCCC) and its Kyoto Protocol. The Vatican is the only C neutral state. Iceland, New Zealand, Norway, and Costa Rica were the first four countries to join the Climate Neutral Network, launched in 2008 by the United Nations Environment Programme (<http://www.unep.org/climateutral>). Costa Rica aims to reach C neutrality by 2021, Norway by 2030, and New Zealand in 2025–2040.

Governmental initiative is important to provide leadership and to foster the implementation of innovative solutions to reduce atmospheric C. It is important that offsetting is not viewed as encouraging ethical carelessness but attributing climate responsibility and credibility to the term “C neutrality.”

C sequestration is a method of net emission reduction that is immediately available using nature's technology. Early action increases the likelihood of avoiding the most severe consequences of global climate change according to the findings of the Intergovernmental Panel on Climate Change Fourth Assessment Report: Climate Change Mitigation.^[1] Sustainable land use improves land health, making it more capable of tolerating changes of future climate. When using soil C sinks, it is important to consider multiple objectives, avoiding large-scale monotonous plantations limited to climatic benefits, being aware of the issue of land rights and

having a clear focus on social justice. Voluntary emission goals can have more “value-added” attributes than those within international agreements or the compliance market such as developmental aims and environmental/sustainability benefits.

Financing revegetation is relatively cheap compared with the other more experimental projects. The Stern report was very particular about the importance of forestry and land use to the climate debate and to climate change mitigation, as a highly cost-effective way of reducing GHG emissions and with a potential to offer significant reductions quickly.^[2]

The time frame of achieving C neutrality may be difficult to envision. Over what time frame does the amount of C emitted have to be fully offset for the C balance to be zero? This depends very much on the balance between emission reductions, the rate of technological development and its employment, and the potential rate and amount of C sequestration.

THE ICELANDIC PROFILE

Iceland offers a good example of a country which could become C neutral within a few decades by combining reductions of emissions and restoring land quality for multiple benefits including C sequestration on some of the vast areas in Iceland that have become degraded over the 20th century.

The profile of GHG emissions for Iceland is unusual in many respects (Fig. 2).^[3] Firstly, electricity production and space heating are based on renewable energy sources (80% of total energy budget), resulting in very low emissions from these sectors. Secondly, more than 80% of emissions from the energy sector stem from mobile sources (transport, mobile machinery,

Fig. 1 C neutrality, which refers to that GHG emissions to the atmosphere are reduced as much as possible, and the remaining emissions are offset.

and fishing vessels). Thirdly, emissions from the land use, land use change and forestry sector are relatively high. Also, research has indicated that there are significant emissions of carbon dioxide (CO₂) from drained wetlands.^[3]

The Potential for Sequestration

The potential for sequestration lies in the land areas that could be revegetated for which the predominant soil type in Iceland is Andosol, which has a capacity to immobilize atmospheric CO₂. Iceland has suffered from severe soil erosion from the time of its settlement (874 A.D.; Fig. 3).

Fig. 2 Emissions of GHGs in Iceland by UNFCCC sector in 2007.

Source: From Arnalds, Thórarinsdóttir, et al.^[4]

Areas with considerable to extremely severe erosion cover about 40% of the country.^[4] In Iceland, C sequestration due to revegetation amounted to 534 Gg CO₂ or 12% of total emissions in 2007.^[3] These C offsets can potentially be increased significantly.

Revegetation in Iceland refers to restoring vegetation on barren land that has no agricultural value, leading to self-sustainable ecosystems with greatly improved ecosystem services. This land cannot recuperate on its own and needs managerial input to overcome ecological thresholds. Reclamation of soil and vegetation on eroded land is therefore considered to be a win-win strategy, linking restoration of soil fertility, biodiversity, ecosystems and their services, increased food security, and habitat conservation.

The legal basis and requirements for emission reduction in Iceland are weak. No laws or regulations cover commerce of C credits, and thus, no national C market is in place. This prevents land users and large-scale emitters in cooperating toward lowering emissions of GHG through C sequestration and therefore needs to be remedied.

Financial assistance or incentives are important for stimulating land improvement. This could include the following:

1. Strengthening policies and measures (the legal basis)
2. Direct policy changes, reclassifying subsidies, land-use zones, or indirect policy changes, e.g., changes in agricultural programs
3. Economic incentives, e.g., payments for environmental services, or disincentives, e.g., taxes
4. Direct infrastructure changes, e.g., damming of canals on peat land

A description of some of the means in use (but could be enhanced) or possibilities that could be employed to increase C sequestration in Iceland is detailed in the following sections.

Sustainable Land Use, Cooperation with Farmers, and Funding

“Regulation on sustainable utilization of land” is important to establish a code of practices for both public and private lands. In 2000, the Icelandic government and sheep farmers signed a voluntary contract on quality control in agriculture, including sustainable land use for which farmers can receive up to 22.5% more subsidies. If the land use criteria were applied stringently, they could lead to land improvement with associated increase in C sequestration.

The “Farmers Heal the Land” project provides incentives for better land health, assisting farmers to halt erosion, revegetate degraded land, and make it available

Fig. 3 Erosion escarpments at Arnardrangur in W-Skaftafellssýsla County show vividly the magnitude of soil erosion. The erosion has resulted in the complete removal of the soil profile down to bedrock or the lava surfaces, leaving isolated islands or areas with some remaining soil and degraded vegetation. The complete lack of vegetation on the eroded surfaces shows that erosion in this site is severe.

Source: Photo from Björn Barkarson, Soil Conservation Service of Iceland.

for sustainable use. The Soil Conservation of Iceland cooperates with 25% of Icelandic farmers in this program, providing consultation and financial support for seed and fertilizer, whereas farmers perform the actual work.

The “Land Improvement Fund,” “Landbótasjóður,” aims to move responsibility, initiative, and execution of soil conservation projects to local authorities, land owners, and non-governmental organizations. The Soil Conservation Service of Iceland provides consultation, funding, and supervision of projects.

Afforestation

Afforestation of treeless landscapes results in net C sequestration in biomass. In 1990, the woodland cover was 1% in Iceland and has great potential to be increased. In 2005, sequestration by woodlands amounted to 78 Gg CO₂ or 1.7% of total national emissions.^[3] In the forestry legislation, the goal is set to increase woodland cover to at least 5% of the lowland surface area below 400-m altitude by 2050.

Restoration of Wetlands

Extensive drainage of wetlands occurred in Iceland for cultivation purposes between 1945 and 1985 due to governmental subsidies. Some of the drained wetlands are used for cultivation or grazing, while others have been abandoned. Conditions for wetland restoration in Iceland are considered favorable, as most of the drained wetlands have not been intensively cultivated. Research has shown that reclaimed wetlands can sequester C, while drained wetlands are big emitters of CO₂. These drained wetlands emit about 1800 Gg CO₂ yr⁻¹, which

was calculated using UNFCCC default emission factors. A typical undisturbed wetland in Iceland sequesters about 0.051–0.099 Gg CO₂ km⁻² yr⁻¹ (H. Óskarsson, 2007, personal communication). If, for example, half of this land was to be restored, instead of emitting 900 Gg CO₂ yr⁻¹, the land could potentially sequester about 120–220 Gg CO₂ yr⁻¹. Restoration activities should be subsidized to speed up the recovery, thereby halting emission from drained wetlands, preventing nutrient loss from the land, and thereby restoring the land for future use.

C Sequestration with Geological Processes

Additional possibility is geological C sequestration. Mineral sequestration studies are underway in Iceland attempting to dispose the CO₂ emissions associated with geothermal energy production. Reinjection of CO₂-saturated fluids into wells or basaltic aquifers can acidify the groundwater, which may be neutralized by water–rock reactions and precipitation of carbonate minerals, thereby sequestering CO₂ as a solid phase in basalt.

CONCLUSION—CAN C NEUTRALITY BE ACHIEVED?

The global process of climate change may influence ecological, economic, and social activities and development at the regional and local level in all countries, making it one of the more profound challenges to sustainable development and poverty eradication.

The goal of C neutrality can only be achieved in a positive political environment. The climate issues have gained

higher visibility at the international and national scales. Increased public interest and scientific evidence for climate changes may prioritize funding for mitigation actions concerning climate issues.

Iceland may have the option of becoming a C neutral country, with emission reductions, with its renewable energy resources, with the vast potential for C sequestration by the restoration of degraded land, and with its more sustainable land use. Options need to be explored in a synergic manner, reaching other environmental and social goals at the same time. C offsetting is not the one and only panacea, but a way forward that is immediately available until new technology leads the way toward low-C societies. Iceland has been used here as an example; elsewhere, other options are likely to be more applicable toward achieving C neutrality.

Carbon Sequestration: Nutrient Management

M.C. Manna

Muneshwar Singh

R.H. Wanjari

Asit Mandal

A.K. Patra

Indian Institute of Soil Science, Bhopal, India

Abstract

The carbon (C) sequestration is a cost-effective strategy to mitigate climate change during the first few decades of the 21st century. There are five global C pools, and the third largest pool exists in soil and is estimated at 2.5 trillion tons (1-m depth). The conversion of natural ecosystems to agricultural ecosystems disturbs the soil ecological balance, soil processes, organic C, and biotic C pools. Extractive farming practices, low external inputs, and soil degrading land use all deplete terrestrial C pools. Approximately, 1.6 Pg C yr⁻¹ depletion can be attributed to deforestation and land use change in agriculture. In tropical agriculture, the application of manures at 10–15 Mg ha⁻¹ yr⁻¹ along with nitrogen, phosphorus, and potassium (NPK) increased soil organic C sequestration at the rate of 50.7–900 kg ha⁻¹ yr⁻¹ over 28–33 years of management. Globally, agricultural soils are estimated to potentially sequester 0.4–0.8 Pg C yr⁻¹ by the adoption of recommended management practices on croplands, 0.01–0.03 Pg C yr⁻¹ on irrigated soils, and 0.01–0.3 Pg C yr⁻¹ on grasslands. In rangelands, integrated nutrient management in horticulture crops, C sequestration rate was estimated at 58–1190 kg ha⁻¹ yr⁻¹. Improved nutrient management in existing agroforestry system sequestered C about 0.012 Tg C yr⁻¹. Globally, there is a C crisis in soil especially in tropical and subtropical ecosystems because of increased carbon dioxide emissions from soil. Therefore, there is huge challenge to maintain the soil C status. Nutrient management is a viable option for soil C sequestration and the mitigation of C emissions.

INTRODUCTION

The increase in concentration of greenhouse gases in the atmosphere is a major threat to agricultural food security and climate change in the 21st Century. Anthropogenic activities have led to notable changes over the 20th century in the earth's climate including the increase in global temperature by $0.6 \pm 0.2^{\circ}\text{C}$ at an average rate of increase of $0.17^{\circ}\text{C}/\text{decade}$. Since 1950, there has been a rise in sea level by 0.1–0.2 m, increase in precipitation by 0.5–1.0%/decade, coupled with an increase in frequency of extreme events and heavy precipitation by 2–4% over the 20th century.^[1] The conversion of natural ecosystems to agricultural and forestry ecosystems can disturb the natural ecological balance, carbon (C) pools, soil processes, and biotic C pools. Tropical and subtropical ecosystems have a great impact on global C cycle, environmental concerns, and socioeconomic issues. The numerous experiments from around the world have demonstrated that the conversion of tropical ecosystems to agricultural, pastoral, and silvicultural land uses substantially enhanced soil C pools. The magnitude of this variation, however, depends on the method of removing the

natural vegetation, agronomic practices, soil and nutrient management, and cropping systems.

C sequestration is an important strategy for the mitigation of climate change effects by means of storing C in soils and biomass. Soil cultivation with agricultural production may lead to significant loss of C from soil.^[2] Stagnating and declining crop yields are attributed to decline in soil quality caused by removal or burning of crop residues, imbalanced fertilization, and inappropriate use of irrigation water. Most agricultural soils have lost 50–70% of their original soil organic carbon (SOC) pool, and the depletion is exacerbated by further soil degradation and deforestation/desertification.^[3] The restoration of degraded soils, the conversion of agriculturally marginal lands to appropriate land use, and the adoption of recommended management practices (RMPs) on agricultural soils can reverse the land degradative trends and lead to SOC sequestration. Technological options for C sequestration on agricultural soils include adoption of conservation tillage, use of manures, and compost as per integrated nutrient management, precision farming strategies, conversion of monoculture to complex diverse cropping systems, meadow-based rotations winter cover crops, and

establishing perennial vegetation on contours and steep slopes. Proper soil and nutrient management may play key role for improving the C sequestration in the soil. The impact of ecosystem processes on global C cycle is comprehensive, but systematic information is needed on soil nutrient management for C sequestration. The objective of this entry is to discuss global C potential and its importance in agriculture and to discuss the best nutrient management practices for enhancing soil C sequestration in agriculture.

GLOBAL C POTENTIAL

There are five global C pools of which the largest oceanic pool is estimated at 38,400 Pg and is increased at the rate of 2.3 Pg C yr⁻¹ followed by the fossil/fuel (4130 Pg). The third largest pool is in the pedologic soil and is estimated at 2500 Pg to 1-m depth. The biotic pool is 602 Pg, and atmospheric pools are estimated at 800 Pg. The soil C pool has two distinct components: SOC pool estimated at 1550 Pg and soil inorganic C pool at 950 Pg.^[4] The SOC pool includes highly active humus and relatively inert charcoal C. Most methods for determining SOC do not account for resistant forms, such as inert charcoal, and thus, they find it difficult to quantify this source of organic C in global C budgets.

IMPORTANCE OF TERRESTRIAL C POTENTIAL

C concentration in the atmosphere is increasing at the rate of about 4 billion tons (2 parts per million) per year with transfer primarily from the fossil fuel, biotic, and soil pools. Fossil fuel combustion emits about 8 million t C yr⁻¹ annually, and deforestation and land use conversion emit another 1.6–2 million t C yr⁻¹, for a total of 9.6–10.80 billion t C emission yr⁻¹. Thus, roughly 8% C being photosynthesized by the biosphere is retained in the soil and biotic pools.

The long-term use of extractive farming practices and conversion of natural ecosystem into crop lands decline in soil quality and exacerbate food insecurity. Therefore, judicious use of fertilizer and integrated nutrient management as well as application of biosolids and other agricultural waste are of paramount importance to improve soil health, nutrient use efficiency, and crop productivity; to increase soil biodiversity; and to enhance the environment quality. Hence, the rate of soil C sequestration depends on the use of precious inputs such as crop residues, fertilizer, manure, compost, and good quality of irrigation water for which farmers must be compensated. Rate of SOC sequestration (kg ha⁻¹ yr⁻¹) may be 500–1000 for croplands, 50–500 for grazing lands, and 2–10 as pedogenic carbonates in drylands.^[5]

C SEQUESTRATION POTENTIAL UNDER DIFFERENT NUTRIENT MANAGEMENT IN AGRICULTURE

C emissions from agricultural activities contribute to enrichment of atmospheric carbon dioxide (CO₂), but C sequestration in agricultural soils, through the use of proper management practices, can mitigate this trend. Different sources of organic, either alone or with, chemical fertilizer application enhance C sequestration potential in arable crops, agroforestry, forage and fodder, and horticulture crops.

Nutrient Management in Arable Cropping System for C Sequestration

The restoration of SOC pool in arable lands represents a potential sink for atmospheric CO₂. The cropping system and soil type influence crop biomass under different fertilizers and manures application. Data from different long-term field experiments on rice–wheat, maize–wheat, soybean–wheat, sorghum–wheat, rice–wheat–jute, and maize–wheat–cowpea were analyzed to assess the impact of fertilization practices on soil C sequestration rate in Inceptisols, Alfisols, and Vertisols (Table 1).^[2,6–13] Long-term application of NPK or farm yard manure (FYM) significantly increased the C sequestration rate in rice–wheat system (55% higher SOC in FYM plots and 70% higher in NPK plots) than in maize–wheat cropping system.^[6] The incorporation of green manure with FYM sequestered relatively low organic C as compared to green manure with FYM and crop residue. Manna et al.^[14] observed that C sequestration rate was greater in Vertisol followed by Inceptisol than Alfisols under integrated nutrient management.

The humification process can be severely constrained by the lack of N, P, sulfur, and other building blocks of soil humus. The efficiency of C sequestration is reduced when C and N are not adequately balanced.^[14,15] Therefore, the SOC sequestration rate is enhanced by an increase in the application of biomass C and N.^[16] Liebig et al.^[17] observed that high N rate treatments increased C sequestration rate by 1.0–1.4 Mg ha⁻¹ yr⁻¹. The application of FYM at 10–15 Mg ha⁻¹ yr⁻¹ along with NPK increased SOC sequestration at the rate of 50.7–900 kg ha⁻¹ yr⁻¹ over 28–33 years.^[2,6–8,11,14]

Some of the strategies for enhancement of C sequestration potential are no-till farming with crop residue mulch and cover cropping (conservation agriculture), integrated nutrient management including use of compost and manure, and liberal use of biosolids. Globally, agricultural soils are estimated to potentially sequester 0.4–0.8 Pg C yr⁻¹ by adopting conservation agricultural practices, which represent 33.3–100% of the total potential of C sequestration in world soils.^[18]

Biofertilizers are an essential component of organic farming. They contain living microorganisms that

colonize the rhizosphere and promote plant growth by increasing the supply of nutrients through N fixation or enhancing the availability of primary nutrients to the host plant by solubilizing P and other nutrients. The microorganisms in biofertilizers restore the soil's natural nutrient cycle and help in building soil organic matter. The studies indicated that biofertilizers sequestered about 1.4 t C ha⁻¹ yr⁻¹.

Several experiments in Europe have shown that the rate of C sequestration is greater with the application of manure than chemical fertilizer alone. Long-term use of manure when compared with chemical fertilizer was found 10% to have greater C sequestration over 100 years in Denmark,^[19] 100% over 144 years in Rothamsted,^[20] and 44% over 21 years in Sweden.^[21] Uhlen and Tveitnes^[22] reported that manure application would increase SOC sequestration at the rate of 70–227 kg ha⁻¹ over 37–74 years.

For sustainability of intensive cropping systems, it is desirable to grow a sequence of crop on a soil type. For example, rice or wheat crop sequence in Indo-Gangetic

Plain has to be replaced by introducing legume crops in the system in different ways like replacing rice by pigeon pea (*Cajanus cajan* L.) in summer or wheat by lentil in winter or introducing a summer green manure crop dhaincha (*Sesbania aculeata*) after the harvest of wheat and before the planting of rice. Growing of pea (*Pisum sativum* L.) or pigeon pea as compared with maize and gram or black gram as compared with soybean (*Glycine max* L. Merrill) substantially increased SOC.

Nutrient Management in Grassland and Fodder Crops for C Sequestration

The disturbance of grassland by means of removing biomass, changing the vegetation, or altering soil function is an integral part of traditional grassland management systems. Practices like overgrazing and burning can also deplete C sequestration in grassland systems.^[23] Harvesting a large proportion of plant biomass increases yields of useful material but at the cost of C inputs to the soil.^[24] It is widely accepted that continuous excessive grazing is

detrimental to plant communities and soil C sequestration.^[25] When management practices deplete the reversed soil C stocks, grassland ecosystem C stocks can be rebuilt and sequester atmospheric CO₂.^[26]

Agriculture management techniques such as livestock forage production also have the potential to augment soil C stocks through fertilization, irrigation, intensive grazing management, and sowing of favorable forage grasses and legumes. The global potential of SOC sequestration is estimated at 0.6–1.2 Pg C yr⁻¹, comprising 0.4–0.8 Pg C yr⁻¹ through the adoption of RMPs on cropland soils, 0.01–0.03 Pg C yr⁻¹ on irrigated soils, and 0.01–0.3 Pg C yr⁻¹ through improvements of rangelands and grasslands.^[27] The synthesis by Smith et al.^[23] suggest that adding manure or biosolids to soil could sequester C at the rates of between 0.42 and 0.76 t C ha⁻¹ yr⁻¹ depending on the region. A comparison of C sequestration of different grassland and fodder crops is presented in Table 2.^[28,29] The potential for C sequestration by *Vetiveria zizanioides* was the highest (15.24 Mg ha⁻¹ yr⁻¹) followed by oat–maize fodder–wheat–soybean in rotation (8.56 Mg ha⁻¹ yr⁻¹). The ryegrass–fodder followed by rice–soybean in rotation substantially improved C sequestration (8.44 Mg ha⁻¹ yr⁻¹).

Nutrient Management in Horticultural Crops for C Sequestration

Management practices for horticulture are more complex because of multiple species possessing varied phenological, physiological, and agronomic requirements. The conversion of long-term arable cropland to agro-horticulture resulted in a significant increase in C sequestration (Table 3).^[9] Under a system of different intercropped fruit trees, the cultivation of fruit trees—i.e., coconut (*Cocos nucifera* L.) intercropped with guava (*Psidium guajava* L.)—enhanced the soil biological activities approximately twofold after 38 years over 10 years of the same intercropped system, and C sequestration rate varied

from 58 to 373.0 and 160 to 1190 kg ha⁻¹ yr⁻¹ after 38 and 10 years, respectively.^[9]

Nutrient Management in Agroforestry for C Sequestration

C sequestration in agroforestry systems can be broadly divided into sequestration in aboveground and below-ground plant parts. The aboveground C sequestration rates in some major agroforestry systems around the world are highly variable, ranging from 0.29 to 15.21 Mg ha⁻¹ yr⁻¹^[30] and differ greatly depending on a number of factors, such as the agroclimatic region, type of system, site quality, previous land use, and management practices adopted. Agroforestry enhances C uptake by lengthening the growing season, expanding the niches from which water and soil nutrients are drawn and, in the case of N-fixing species, enhancing soil fertility. Improved management in existing agroforestry systems could sequester 0.012 Tg C yr⁻¹, while conversion of 630 million hectares of unproductive or degraded croplands and grasslands to agroforestry could sequester as much as 0.59 Tg C annually by 2040.^[31]

In a typical agroforestry system, about 69% of soil C in the profile was confined to the upper 40 cm soil layer wherein C stock ranged from 0.87 to 13.7 Mg C ha⁻¹ yr⁻¹ (Table 4).^[32] In a *Leucaena* agri-silvi system, C sequestration was the highest (13.7 Mg C ha⁻¹ yr⁻¹) followed by *Prosopis* silvi-pasture system (2.36 Tg C ha⁻¹ yr⁻¹). A mix of agroforestry with crop fields is a promising option to enhance C sequestration in soils. In general, agroforestry

systems on the arid, semiarid, and degraded sites have a lower C sequestration potential than those on fertile humid sites, and the temperate agroforestry systems have relatively lower sequestration potential compared with the tropical systems under conservation agriculture. In agroforestry systems, the C stored in soil ranged from 30 to 300 Mg C ha⁻¹ up to 1-m depth.^[30]

FUTURE RESEARCH

Soil-stabilized C is the key component for enhancing soil quality. It could mitigate soil degradation caused by several biotic and abiotic factors. C sequestration in tropical ecosystems remains a challenging task for soil scientists. In this context, proper action, such as increasing SOC storage through adoption of RMPs, should be taken to save our soil from the soil degradation. These practices include no-till farming, compost on soil, legume-based rotations, use of mulch farming and conservation tillage, integrated nutrient management and manuring, implementation of agroforestry systems, restoration of eroded and salinized soils, and conversion of agriculturally marginal lands into restorative land uses. A natural way of C conservation can be achieved through maximum organic residues, cover crops, and no-tillage and with minimum emissions from fossil fuel combustion. Further, there is an additional potential of C sequestration in biomass especially by forest and other biota. Biosequestration of C, both by soil and by biota, is a truly win-win situation. While improving crop biomass productivity, these options also improve water quality and mitigate climate change by reducing the emission of CO₂ from soil.

Carbon Sequestration: Sediments

Eswaran Padmanabhan

Geoscience, University Teknologi Petronas, Bandar Seri Iskandar, Malaysia

Abstract

The rise in global temperatures over the last few decades has been linked to the unprecedented increase in greenhouse gases. Storage or elimination of produced carbon dioxide (CO₂) has become a challenge since the 1970s. Various methods and options exist that will cater to excess C being removed from the ecosystem. However, the relative stability of these options is a challenge to the sequestration team. Sediments in onshore areas can be found in several types of environments. Of these, wetlands are recognized as being able to hold at least a quarter of the global organic C content. Spatial and temporal variability in C contents as well as sequestration potential are important issues to be considered when dealing with sediments as a sequestration media. Offshore methods have a different set of challenges. The density and dissolution kinetics of CO₂ are critical in determining a proper sequestration with minimal need for postinjection monitoring for leakages. Despite advances in technology, public perception of sequestration projects is not devoid of skepticism and distrust. The main concerns revolve around release of large amounts of CO₂ into the natural waters or atmosphere culminating in irreparable damage to the ecosystem. As the production of CO₂ is projected to increase with time, it is inevitable that management policies and strategies need to be reformulated in order to successfully curb the impacts of excess CO₂ in the atmosphere.

INTRODUCTION

Global temperatures are rising. The temperature increase has been linked to more intense precipitation events, decrease in ocean thermohaline circulation, and also rising sea levels due to glacial melting. Rising sea levels can cause flooding of low-lying coastal areas that can result in loss of life and property. Global temperature increase could also affect global ecosystems resulting in unpredictable plant distribution and colonization, extinction of several species, and cause outbreaks of diseases.

The study of ice cores from the Antarctica has established a strong relationship between increase in atmospheric temperature and rise in carbon dioxide (CO₂) content in the air. Studies have shown that as temperature rises, solubility of CO₂ in oceans decreases thereby inducing CO₂ to diffuse out of the oceans. This increases the concentration of CO₂ in the atmosphere. Therefore, it is important to know the best means of reducing CO₂ concentration in the atmosphere. One such way is known as CO₂ sequestration.

Carbon (C) is sequestered naturally in soils and sediments. The distinction between soils and sediments lies in the ability of the former to sustain life. The term “sediment,” on the other hand, is traditionally reserved for loose and unconsolidated material that is found at the earth’s surface. In terms of sequestration, there is a lot of similarities in the mechanisms of accumulation, storage, sequestration, and eventually depletion through destruction.

Storing CO₂ in deep-sea sediments was first proposed by Koide et al.^[1] who proposed storing a mixture of CO₂, clay, ash solutions, and CO₂(l) in three depth regimes: 1) shallow subseabed (shallower than 300 m); 2) deep subseabed (300–3,700 m); and 3) super deep subseabed (more than 3,700 m).

This entry focuses on C sequestration in sediments and excludes any discussion of sequestration at or above the ocean floor.

C SEQUESTRATION IN TERRESTRIAL SEDIMENTS

Cultivation of soils causes depletion of organic C pool. This depletion is explained as being due to oxidation or mineralization due to breakdown of aggregates leading to exposure of C, and change in temperature and moisture regimes,^[2,3] leaching and translocation as dissolved organic C or particulate organic C,^[2] and accelerated erosion by water runoff or wind.^[4,5]

In coastal environments, it is believed that a significant fraction of CO₂ is sequestered for centuries by certain coastal habitats, e.g., seagrasses, mangroves, and salt marshes. These systems should be managed and conserved for C sequestration. However, these coastal systems are being lost due to pollution and mismanagement. Thirty-five percent of the mangrove systems in the world have been lost while about 29% of the seagrass system globally have been lost. Annual loss of coastal systems is estimated

at about 2%. This loss basically means that a very efficient and natural C mitigation mechanism is being lost gradually.

Degradation of the coastal ecosystems initiates a rapid release of stored C. It has been estimated that draining a coastal wetland such as a marsh or a mangrove releases about $0.25 \text{ Mt CO}_2 \text{ km}^{-2} \text{ m}^{-1}$ of sediment lost.

The estimated C stocks in salt marshes are about $1.3\text{--}4.9 \text{ t C ha}^{-1}$ for material above the ground and about $0.9\text{--}13.9 \text{ t C}^{-1}$ for below the ground biomass. Measured C contents are somewhat higher in their values compared to the estimated values. Unfortunately, the exact areal extent of these marshes worldwide is unknown. In addition to that, the exact sequestration and mechanism of C dynamics in such systems are also poorly understood.

Deserts on the other hand have been estimated to have a mean C content of 64 t C ha^{-1} .^[6] It is recognized that the C stocks in deserts can be high since the aridity perturbs microbial decomposition (typical stocks of $14\text{--}270 \text{ t C ha}^{-1}$). Naturally, deserts in tropical environments have lower stocks compared to temperate and boreal regions. However, the C balance in deserts remains a gap in knowledge.^[7]

Wetlands occupy about 5% of the land globally and are typified by water-logging conditions. Productivity among wetlands varies depending on the type of the wetland, climatic condition, and vegetation communities. Climate (temperature and moisture enhanced microbial activity) and quality (composition) of organic matter determine the accumulation potential of C in wetlands. These characteristics make wetlands one of the most effective ecosystems for storing soil C.^[8] Wetlands may hold up to 20–25% of world's organic C.^[9] Since C fluxes and pools are spatially and temporally variable in different types of wetlands, the actual quantity of C stored in each system also varies.

Peat lands (Fig. 1) sequester significant quantities of the world's C. The total amount of C in standing vegetation and peat soil has been estimated between 20% and 35% of the

Fig. 1 Peatlands being cleared for land development.

total terrestrial C.^[10] It has been estimated that northern peat lands alone contain more than 500,000 million tons of C. Many peat lands produce only 20% of the methane produced by shallow water wetlands.^[10] In addition, processes vary at different levels with a peat deposit. The lower levels of peat produce methane while the upper levels at least partially oxidize methane released from the lower levels. Although drainage of peat lands has been shown to reduce methane production, other studies have indicated that this may be more than compensated by the methane production in the associated drainage ditches. CO_2 release will increase dramatically to levels as high as $15 \text{ t C ha}^{-1} \text{ yr}^{-1}$ in the temperate zone and $50 \text{ t C ha}^{-1} \text{ yr}^{-1}$ in the tropics through decomposition of peat after drainage.^[11]

River microterraces can show large variations in the amount and type of C sequestered. In Malaysia, a river terrace sequence developed from the weathered sediments of granite and sedimentary sequences shows differences in height as well as internal drainage.^[12] The sediments in this terrace were grouped (Fig. 2) under three classes: 1) low-level microterrace (drainage classes ranging from poor to very poor drainage); 2) intermediate-level microterrace (drainage classes ranging from well-drained to moderately well-drained drainage); and 3) high-level microterrace (drainage classes ranging from somewhat imperfectly drained to somewhat poorly drained drainage).

The sediments of the low-level terrace have very low C contents. The upper layers are dominated by clay whereas fine sand dominates layers below the lithologic discontinuity. Porosity and clay percentage decreases with depth. In accordance with this, the moisture retained has a general decreasing trend with depth as well. High amounts of moisture retained at the surface horizons are attributed to the high organic C content. The surface horizon has a high organic matter content which decreases with depth. In a slightly elevated position, the sediments still experience poor drainage conditions. In most parts, the sediment has a clayey texture. The surface horizon has a high content of organic matter typically about 4%. Lower horizons have very low organic matter. The high concentration of organic

Fig. 2 Variation of internal drainage in sediments of river terraces. The figure also illustrates the type of land use practiced in Malaysia.

matter in the surface is attributed to poor drainage conditions.

In the intermediate-level microterrace, the sediments have a somewhat poorly drained internal drainage. The surface horizon is exposed to seasonal flooding and water logging. The material is generally clayey and is subject to fluctuating water tables. In situations where drainage may improve locally, the sediment would have a much lower organic matter content compared with the lower microterrace level sediments. This indicates that drainage has a control on the amount of organic matter and C in terraces. Organic matter decreases with depth. The water retention at various pressures and available water are quite low in the top horizon and change erratically with depth. This has been attributed to the decreasing clay contents.

Sediments at the high-level microterraces have better internal drainage. The internal drainage is classified as somewhat imperfectly drained. This material has a clayey surface layer and a lighter textured subsurface layer. Organic matter content shows a maximum at the surface with concomitant decrease with depth. The sediments here have generally a much lower organic matter content compared to all other topographic positions discussed so far. This is attributed to the better drainage conditions thereby inducing better turnover of the organic matter.

An alternative technology is being tried out. The application of biochar (charcoal or biomass-derived black C) could lead to a significant, long-term sink for atmospheric CO₂ in terrestrial ecosystems. Biochar apparently improves fertility and increases crop production. Application of biochar could lead to sequestration of about 50% of the initial C compared to the 3% or less amounts retained after burning. The C derived in this manner is claimed to be more stable than those derived from burning or direct application of biomass on land.

C SEQUESTRATION IN MARINE SEDIMENTS

CO₂(l) is denser than water at high pressures and low temperatures due to its high degree of compressibility. It has been stated^[13] that the injected CO₂(l) at depths of 3,000 m sinks and forms a lake of CO₂(l) on the seafloor. Ocean currents can mix the injected CO₂(l) and release the CO₂ into the atmosphere.^[14] The combination of high pressures and low temperatures that is needed to compress CO₂(l) to a density greater than the pore fluid creates a condition that is similar to the condition necessary for CO₂ hydrates to form. The region where this condition exists is also known as the hydrate formation zone (HFZ). The HFZ starts from this point and extends downward until the temperature rises above the boundary of the hydrate stability field.^[15]

In order to prevent this from happening, CO₂ is to be injected below the seafloor. The injected CO₂ is denser than the pore fluids. This difference in density creates a buoyancy effect that results in gravitational stability.

Subsequent to injection, the CO_{2(g)} will slowly dissolve into CO_{2(aq)} that is denser than the surrounding pore fluid.^[16] CO₂ requires a lot of pore fluids to fully dissolve. Interaction of this CO₂ with calcareous sediments in the host rock determines the CO_{2(aq)}, H₂CO₃, HCO₃⁻, and CO₃²⁻ balance. The total dissolution of carbonate minerals is predicted to be small (i.e., <1%) before the pore fluids become saturated. After injection, the CO₂(l) injected below the HFZ is expected to flow upward until it reaches the bottom the HFZ.^[15] These authors believe that CO₂ hydrates will form once the CO₂(l) reaches the bottom of the HFZ. The formation of the hydrates tends to clog up pore channels thereby creating a cap of limited permeability. Additional CO₂ flowing up from the injection point is expected to become physically trapped beneath the hydrate cap.^[15] This trapping mechanism forces the additional CO₂ to spread laterally thereby resulting in a larger storage area.

The stability of the hydrates is maintained as long as it is in contact with pore fluids saturated with CO_{2(aq)}. It has been clarified further^[15] that if the CO₂(l) to CO_{2(aq)} dissolution kinetics were rapid, then the pore fluid in contact with pure CO₂(l) plume will be saturated in CO_{2(aq)} until the entire plume of CO₂(l) dissolves. As such, they stated that the CO₂ hydrate cap will not dissolve until the CO₂(l) plume has fully dissolved.

ENVIRONMENTAL IMPACTS

C sequestration has been perceived with mixed feelings by the society. The main concerns have been with long-term stability of seals in sequestration projects, impact on fauna and flora, as well as stability of coral platforms and geological storage media. In addition to this, there has been some concern about sudden release of CO₂ plumes into the atmosphere from both offshore and onshore sequestration sites. These concerns have been the reason for a leap in technological advancements designed to minimize these effects.

In the initial stages, it was estimated that a large quantity of CO₂ may be dissolved in deep ocean waters. These estimates were made at a time when the knowledge on ocean biogeochemistry was still incomparable to the wealth of information we had. We know that the pH of the surface ocean has been reduced by approximately 0.1 units since preindustrial times. Further addition of C into the ocean is estimated to decrease the average ocean pH by about 0.3 units. Studies have shown that the pH of the ocean waters increases away from the point of injection. The nonswimming marine organisms (e.g., zooplankton, bacteria, and benthos) residing at depths of about 1,000 m or greater will be affected by both the level of pH change and the duration of exposure to the lowered pH conditions. As such, it is pertinent that any sequestration of CO₂ in marine environment be done preferably in deep sediments or sedimentary formations.

Therefore, it is evident that environmental impact assessment is very important in any sequestration project. Ultimately, this may also be the most important factor that determines the viability of any sequestration projects in offshore areas. The viability of such projects also depends on social and political considerations and that this strategy will require all stakeholders (private, public, and non-governmental organizations) be included in research and development of best sequestration strategies.

MANAGEMENT STRATEGIES TO MAINTAIN/ENHANCE C SEQUESTRATION IN SEDIMENTS

Essentially, it is important that we prevent the release of stored C in sediments as a consequence of mismanagement or mishandling. There obviously is a need to maintain a high sequestration capacity in sediments or enhance the sequestration capacity when the resident capacity is very low. Knowledge obtained from managing soils to increase C sequestration could also be used in managing sediments for the same purpose. The fact that sediments tend to have low contents of C is the first factor that encourages C sequestration. The estimates indicate that sediments could, if other conditions were right, sequester close to 1 Gt C yr⁻¹. Cooler and wetter conditions tend to favor C sequestration. It is also important to remember that the quantity of C stored is finite and the process itself is reversible.

Other techniques to increase C sequestration in terrestrial sediments include mulching, maintaining water balance (moisture), proper nutrient management in cropping systems, implementation of agroforestry practices in suitable areas, abstinence from indiscriminate drainage designs, species introduction, erosion control, and organic as well as nutrient amendments.

Conservation and management of sediments in coastal marine ecosystems could be an efficient and cheap natural method for removing CO₂ from the atmosphere. Regrettably, there are insufficient policies globally at this moment to support the management of sediments of the marine ecosystems to sequester this gas. Some research questions have come forth when considering the sequestration rates of C in these systems. It is unclear as to what is the impact of degradation on the specific sequestration rates. A popular research question asked is how are the sequestration rates and C stocks in sediments affected by climatic changes.

The requirements can only be realized if certain policies are implemented globally. Degradation and loss of natural habitats require urgent attention in many countries, especially in the tropics. Ecosystem resilience in relation to C pools requires a careful assessment through conservation and restoration. This will reduce the instances of desertification in many locations.

CONCLUSION

Onshore sediments tend to behave differently with regard to sequestration. In all cases, moisture and temperature are very important in determining the amount and length of sequestration. Other factors are also recognized. The use of charred materials appears to be an effective means of C sequestration.

The discussion on sequestration in sediments below 3,000 m at high pressure and low temperature suggests a possible permanent solution to CO₂ sequestration problems in offshore areas. The success of this approach requires CO₂ to be present below a layer of more buoyant pore fluid. The existing theories predict that the sequestered CO₂ needs to dissolve into the pore fluids. It is predicted that the dissolving of CO₂ into the pore fluids will take thousands of years. Concurrently, the CO_{2(aq)} will sink that of the pore fluids. If this theory works, then CO_{2(l)} could be stored in deep-sea sediments at high pressures and low temperatures without any investment in monitoring or verification technology. This would then provide untold financial benefits to the industry.

The environmental concerns associated with C sequestration have been received with mixed feelings. Most concerns are with the C being released in huge amounts somewhere in the near future. As outlined in this entry, any abnormal amounts of C released can result in fatality of fauna and flora. Therefore, it is imperative that the technology employed is able to contain the excess C for the intended lengthy period, i.e., to last thousands of years. To achieve this, certain specific management policies are outlined and relevant strategies have to be initiated globally.

Carbon Sequestration: Semiarid Regions of India

Cherukumalli Srinivasa Rao

Sumanta Kundu

Srinivas K.

Central Research Institute for Dryland Agriculture, Indian Council of Agricultural Research (ICAR), Hyderabad, India

Abstract

Severe soil organic carbon (SOC) depletion is a major constraint in semiarid regions of India because it directly influences soil quality, crop productivity, and sustainability. The magnitude of SOC stocks in the semiarid bioclimate is estimated at 2.9 Pg. Sorghum, finger millet, pearl millet, maize, rice, groundnut, soybean, cotton, food legumes, etc. are the predominant crop production systems. Data from long-term experiments on major rainfed production systems in India show that higher amount of crop residue carbon (C) input ($\text{Mg ha}^{-1} \text{ yr}^{-1}$) is returned to soil in soybean–saflflower (3.37) system practiced in Vertisols of central India. The long-term addition of chemical fertilizer and organic amendments improved the SOC stock. For every 1 Mg ha^{-1} increase in SOC stock in the root zone, grain yield (kg ha^{-1}) increased by 13, 101, 90, 170, 145, 18, and 160 for groundnut, finger millet, sorghum, pearl millet, soybean, lentil, and rice, respectively. Long-term cropping without using any organic amendment and/or mineral fertilizers resulted in severe depletion of the SOC stock, which was highest in groundnut–finger millet system ($0.92 \text{ Mg C ha}^{-1} \text{ yr}^{-1}$) in Alfisols. The critical levels of C input requirements for maintaining SOC at the antecedent levels ranged from 1.1 to 3.5 $\text{Mg C ha}^{-1} \text{ yr}^{-1}$, depending on soil type and production system. Promotion of sustainable use of soil and water resources includes prohibiting residue burning, reducing deforestation, promoting integrated farming systems, and facilitating payments for ecosystem services can improve soil quality through increase in SOC sequestration and agronomic productivity of rainfed agroecosystems.

INTRODUCTION

The global area of semiarid tropics or dryland tropics, estimated at around 650 million hectares, covers 55 countries and is home to more than 2 billion people.^[1] According to the latest estimates, global rainfed cropland is 1132 million hectares, which is 2.78 times of the world's net irrigated area (407 Mha).^[2] About three fourths of the area under arid, semiarid, and dry-humid bioclimatic zones is rainfed and accounts for 57% of the net cultivated area in India. These areas contribute to 40% of national food grain production and support two-third of the total livestock population of the country. Rainfed areas contribute the production of 87% of coarse grain cereals and pulses, 77% of oilseeds, 60% of cotton, 90% of soybean, and 50% of fine cereals including rice (*Oryza sativa*), wheat (*Triticum aestivum*), maize (*Zea mays*), and sorghum (*Sorghum bicolor*). Although double cropping in rainfed regions is rare, there is a vast potential of rainfed area in terms of food grain production. Region specific investments and management strategies are required for rainfed agroecologies, as they are complex, diverse, fragile, risk prone, and under-invested. The net sown area in the country was 141.6 Mha during 2010–2011 and it did not increase much during 1970–2010, but the human and livestock populations have been steadily

increasing. The slowdown in productivity growth has been attributed to resource degradation and falling factor productivity in major production systems.

Soil organic carbon (SOC) concentration is a key indicator of soil quality and productivity. Restoring the quality of degraded soils necessitates increasing SOC concentration in the root zone. The term “soil C sequestration” implies removal of atmospheric carbon dioxide (CO_2) by plants through photosynthesis and transfer of biomass C into soil as humus. The strategy is to increase SOC density, improve depth distribution of SOC, and stabilize SOC by encapsulating it within stable microaggregates so that C is protected from microbial processes and has a long mean residence time (MRT). In this context, adopting recommended management practices (RMPs) in agroecosystems that create a positive soil C budget is an important strategy for SOC sequestration. Thus, land use change can be an important instrument for SOC sequestration. However, the SOC sink capacity depends on the antecedent level of SOC, climate, profile characteristics, and management. Incorporation of SOC into the subsoil by establishing plants with a deeper root systems or illuviation through bioturbation and pedogenesis can increase MRT of SOC. The SOC concentration in the surface layer usually increases with increasing inputs of biosolids,^[3] although the specific empirical

relation depends on soil moisture and temperature regimes, nutrient availability [nitrogen (N), phosphorous (P), potassium, and sulfur], texture, and climate. In addition to the quantity of input, quality of biomass can also be important in determining the SOC pool. Most of the research done thus far on SOC sequestration in soils of agroecosystems is confined to cold and temperate regions. Some of the studies were conducted in tropical and subtropical regions of India.^[4–15] The objective of this entry is to synthesize the available information on carbon stocks in different soil types in semiarid India, carbon sequestration scenarios in major rainfed production systems, minimal carbon input requirement for zero change in SOC stock, and important management practices and strategies that influence C sequestration and policy interventions required in Indian context.

SOIL CARBON STOCKS OF DRYLAND AGROECOSYSTEMS IN INDIA

The SOC storage is strongly related to climate (temperature and rainfall). Semiarid bioclimate consists of major parts of central and southern Peninsula, which extends up to western and northwestern part of the country and comprises of 17 agroecological subregions and 7 agroclimatic zones. By and large, mean annual temperature in semiarid bioclimate ranges between 25°C and 27°C and mean annual precipitation (MAP) ranges between 500 and 1000 mm. This bioclimate is characterized by a type of vegetation, which ranges from bushy thorns and grasses to deciduous forests. The total SOC stock in the semiarid bioclimate is 2.9 Pg, which is nearly 30% of the total SOC stock of the country.^[13] SOC stock varied among major rainfed soil types of India. Vertisols and associated soils contain higher carbon stocks, followed by Inceptisols, Alfisols, and Aridisols.^[16] The SOC stocks range from 26.69 to 59.71 Mg ha⁻¹ with a mean of 43.74 Mg ha⁻¹ in Inceptisols, from 23.28 to 49.83 Mg ha⁻¹ with a mean of 30.82 Mg ha⁻¹ in Alfisols, from 28.60 to 95.90 Mg ha⁻¹ with a mean of 46.38 Mg ha⁻¹ in Vertisols, and from 20.10 to 27.36 Mg ha⁻¹ with a mean of 23.73 Mg ha⁻¹ in Aridisols. Vertisols with smectite as dominant mineral have larger SOC stocks than illitic Inceptisols and kaolinitic Alfisols.

CARBON SEQUESTRATION POTENTIAL OF DIFFERENT RAINFED CROPPING SYSTEMS UNDER VARIED NUTRIENT MANAGEMENT

Some of the long-term manurial experiments established in late 1970s to early 1990s under the auspices of the All India Coordinated Research Project on Dryland Agriculture are located in different ecoregions in semiarid climates such as Anantapur (Andhra Pradesh), Bangalore (Karnataka), Solapur (Maharashtra), Indore (Madhya Pradesh), Sardar Krushinagar (Gujarat), and Varanasi (Uttar Pradesh;

Table 1). Common treatments across seven experiments are control (no fertilizer or organics), 100% recommended dose of fertilizers (RDF), 50% RDF + 50% organics, and 100% organics.^[11,13]

Nutrient Management Effects on SOC Stock and SOC Sequestration Rate

Nutrient management plays a vital role on SOC sequestration. Better nutrient management, particularly the application of organics not only increases the carbon input directly but also increases the plant biomass, particularly root biomass. Results from long-term experiments show the highest SOC stock (Mg ha⁻¹) in 50% RDF + 4 Mg ha⁻¹ groundnut shell (47.2), 10 Mg ha⁻¹ FYM + 100% NPK (85.7), FYM + 100% NPK (73.0), 25 kg N (sorghum residue) + 25 kg N (*Leucaena*) (68.5), 50% RDN (fertilizer) + 50% RDN (FYM) (25.5), 6 Mg FYM + N₂₀P₁₃ ha⁻¹ (69.9), and 100% organic (FYM) (27.5) in groundnut (*Arachis hypogaea*), finger millet (*Eleusine coracana*), groundnut–finger millet rotation, sorghum, pearl millet (*Pennisetum glaucum*), soybean (*Glycine max*), and rice-based systems, respectively. Improved nutrient management practices were identified in major rainfed production systems on the basis of the mean rate of SOC sequestration. The average SOC sequestration rate (Mg C ha⁻¹ yr⁻¹) with different management treatments was as follows: 0.57 for 50% RDF + 4 Mg ha⁻¹ groundnut shell, 0.57–0.72 for 10 Mg ha⁻¹ FYM + 100% NPK, 0.65 for 25 kg N ha⁻¹ (sorghum residue) + 25 kg N (*Leucaena* clippings), 0.24 for 50% RDN (fertilizer) + 50% RDN (FYM), 0.79 for 6 Mg ha⁻¹ FYM + 20 kg N + 13 kg P, and 0.32 for 100% organic (FYM) (Table 1).

Productivity Enhancement due to Increase in SOC Stock in the Root Zone

Increase in agronomic productivity through increased SOC stock in the root zone was evaluated in major rainfed production systems. Results showed that 1 Mg C ha⁻¹ yr⁻¹ increase in SOC stock in the root zone led to a significant increase in yield in several rainfed crops. These increases were 13, 101, 90, 170, 145, 18, and 160 kg ha⁻¹ in groundnut, finger millet, sorghum, pearl millet, soybean, lentil (*Lens esculenta*), and rice, respectively.^[11] These increases of yield of different rainfed crops in India are comparable to other parts of the globe under rainfed/irrigated conditions. In most of the cases, these are higher than other findings. For example, an increase in SOC stock by 1 Mg ha⁻¹ increased grain yield by 27 kg ha⁻¹ in wheat in North Dakota, U.S.A.,^[17] 40 kg ha⁻¹ in wheat in the semiarid pampas of Argentina,^[18] 17 kg ha⁻¹ in maize in Thailand,^[19] and 10 kg ha⁻¹ in maize and 1 kg ha⁻¹ in cowpea (*Vigna unguiculata*) in western Nigeria.^[20] Even these increases are much higher compared to irrigated crops in India. For example, Kanchikerimath and Singh^[21] reported

6 kg ha⁻¹ in wheat and 3 kg ha⁻¹ in maize in alluvial soils of northern India. Lal^[17] estimated that adoption of RMPs could increase SOC stock by 1 Mg ha⁻¹ yr⁻¹, which can increase food grain production by 32 million Mg yr⁻¹ in developing countries.

Minimal Carbon Input Requirements for Arresting C Depletion

“Critical carbon input” is the quantity of carbon input required to maintain SOC level of the soil to its antecedent level. This information is important to formulate long-term carbon management strategies. Continuous cropping without using any organic amendment and/or mineral fertilizers causes depletion of the SOC stock. This depletion ranges from 0.15 Mg C ha⁻¹ yr⁻¹ in rice-based system to 0.92 Mg C ha⁻¹ yr⁻¹ in groundnut–finger millet rotation. The highest rate of depletion (0.92 Mg C ha⁻¹ yr⁻¹) was observed in groundnut–finger millet rotation in semiarid Alfisols followed by 0.67 Mg C ha⁻¹ yr⁻¹ in pearl millet-based system in Entisols and 0.47 Mg C ha⁻¹ yr⁻¹ in soybean-based system in Vertisols. The SOC depletion was lowest in rice-based system. There was a negative relationship between mean annual C inputs and mean SOC depletion rates across the locations, soil types, and production systems. However, the MAP plays a significant role in SOC depletion and an inverse relationship exists between MAP and SOC depletion rate. Globally, rates of C sequestration by different types of management ranged from 0.11 to 3.04 Mg C ha⁻¹ yr⁻¹, with a mean of 0.54 Mg C ha⁻¹ yr⁻¹, and are highly influenced by soil type and climate.^[22,23] Total C input including leaf, stubble, root, nodules, and rhizodeposition, as well as external inputs through FYM/groundnut shell/sorghum residue/*Leucaena* clippings, and cumulative C inputs into soil under different treatments during the long-term experiments are given in Table 1. The highest C inputs (6.99 Mg ha⁻¹ yr⁻¹) were added in soybean and lowest 1.86 Mg ha⁻¹ yr⁻¹ in pearl millet system. The positive linear relationship between the changes in SOC stock and the total cumulative C inputs to the soil (external organics plus crop residue) over the years was highly significant and indicates that even after 13–27 years of C input ranging from 0.2–1.9 Mg C ha⁻¹ yr⁻¹ in pearl millet-based system to 1.9–7.0 Mg C ha⁻¹ yr⁻¹ in soybean–safflower system, the C sink capacity was not saturated. Therefore, these severely depleted soils have a high C sink capacity. However, sink capacity and/or sequestration rate cannot continue indefinitely.^[24] Each soil with a different C loading may reach a new steady state of SOC stock over time. The global potential of SOC sequestration and restoration of degraded/desertified soils is estimated at 0.6–1.2 Pg C yr⁻¹ for about 50 years with a cumulative sink capacity of 30–60 Pg (petagram = 10¹⁵ g = billion metric ton),^[23] comprising 0.4–0.8 Pg C yr⁻¹ through adoption of RMPs on cropland (1350 Mha), 0.01–0.03 Pg C yr⁻¹ on irrigated soils (275 Mha), and 0.01–0.3 Pg C yr⁻¹ through improvements

of rangelands and grasslands (3700 Mha). Maintaining a constant level of SOC stock (zero change) requires C input of 1.10 Mg C ha⁻¹ yr⁻¹ in Vertisols under winter sorghum system to 3.47 Mg C ha⁻¹ yr⁻¹ under a soybean-based system. The rate of C input required for groundnut, finger millet, and winter sorghum system is much lower than those reported by Kong et al.^[25] (3.1 Mg ha⁻¹ yr⁻¹) in Davis, California, U.S.A. and 4.59 Mg ha⁻¹ yr⁻¹ by Majumder et al.^[26] for rice–wheat–jute system, 3.56 Mg ha⁻¹ yr⁻¹ by Majumder et al.^[27] for irrigated rice–wheat systems of the Indo-Gangetic plains, and 2.92 Mg ha⁻¹ yr⁻¹ by Mandal et al.^[28] for rice-based system in some soils of subtropical India. The lower input of C needed to maintain a constant level in long-term experiments done in India may be due to lower initial SOC levels (1.4–3.9 g kg⁻¹ soil).^[16] In the abovementioned studies, the initial SOC concentrations were approximately 3 to 6 times higher (>6–15 g kg⁻¹ soil) than those in this entry. In case of soybean, pearl millet, and upland rice, this rate is comparatively higher.^[9–14] In case of soybean–safflower sequence cultivated in Vertisols, initial SOC concentration of the soil was relatively high (6.2 g kg⁻¹). New and well-designed experiments are needed on different rates of biomass C input so that the threshold level can be established for different soils. Similar experiments are needed for deriving the rates of increase in crop yields per unit increase in SOC stock in the root zone.

CARBON MANAGEMENT STRATEGIES

The adoption of appropriate/diversified crop rotations by including legumes in cereal-based systems, balanced use of chemical fertilizers, and integration with organic manures and conservation agricultural practices can maintain the required level of SOC in the soil.^[13] Quantity of soil organic matter is a critical component of soil productivity. Residue management, particularly the retention of full/partial residue along with improved fertilization, can play a significant role in increasing the carbon input into the soil.^[29] However, availability of crop residue is a major problem in India due to competing alternative uses, but in some crops such as groundnut (shells), pigeonpea, cotton, castor, and soybean, residues are available for soil application, as they do not have major alternate uses. However, the application of some of these residues is difficult, as they have very hard stems (pigeonpea, cotton, etc.). Some residues like pigeonpea leaves are difficult to retain in the field, as they easily blown away by wind.

The strategies for a positive C balance are termed as RMPs in comparison with traditional practices in agriculture. Some of these RMPs are alteration of cropping systems, improved varieties with high biomass production, recycling organic waste, judicious use of chemical fertilizers, use of bioamendments, and improved soil and water management. These practices contribute not only toward soil conservation but also enhance the amount of SOC and

reduce CO₂ emissions^[30] as well as maintain a steady state of SOC for longer term.^[31] Conservation agriculture (CA) based on three major principles, namely minimum soil disturbance, residue retention, and crop rotation, is gaining importance day by day as a sustainable crop production technology in the context of increased climatic vulnerability. Experts have recognized its role in C storage and sustainable ecosystem services, but at the same time they have different opinions about C sequestration under CA system.^[15] Although, the adoption of CA worldwide shows a positive C balance in soils according to many case studies,^[22,31] there are several studies that show no change or decrease in SOC stock after practicing CA for several years. It has been estimated that conversion of all cropland to CA globally could sequester 25 Gt C over the next 50 years. This might mitigate C emission to the extent of 1833 Mt CO₂eq yr⁻¹.^[32] The applications of biochar or charcoal also have higher GHG mitigation potential. Many studies suggest that biochar is an effective soil amendment for improving soil conditions and increasing C sequestration.^[33]

Several management options are being promoted by Central Research Institute for Dryland Agriculture in farmer's participatory action mode in Telangana and Andhra Pradesh state. Some RMPs being promoted include crop residue retentions, FYM, biofertilizers, inclusion of legumes in the cropping sequence or as intercrops, green manure crops, green leaf manuring, tank silt addition, and vermicomposting along with chemical fertilizers.^[34] Among them, green leaf manure (GLM) with *Gliricidia sepium* is the most promising technology. *Gliricidia* can thrive in dry moist, acidic soils, or even on degraded soils under rainfed conditions. Growing *Gliricidia* plants on farm bunds serves dual purpose of producing GLM rich in N and in conserving soil.^[34] Farm bunds could be productively used for growing N-fixing shrubs and trees to generate N-rich loppings. For example, growing *G. sepium* at a close spacing of 75 cm on farm bunds could provide 28–30 kg N ha⁻¹ yr⁻¹ in addition to being a valuable source of organic matter.^[35]

Using GLM of *Gliricidia* can enhance soil productivity and increase crop yields of several rainfed crops. Impact of mulch-cum-manuring with *Gliricidia* on the productivity of castor showed a threefold increase compared with that of the control and one-and-a-half-fold increase in comparison with application of FYM and fertilizer. Yield response of different rainfed crops to *Gliricidia* GLM has been positive in many regions including that of finger millet in red soils of Karnataka, groundnut in red soils of Andhra Pradesh, pearl millet in light-textured soils of Gujarat, and sorghum in medium to deep black soils of Maharashtra. At Bhubaneswar, in acid red and lateritic soils, maize yield improved from 1.7 to 2.1 Mg ha⁻¹ by *Gliricidia* GLM equivalent to 20 kg N ha⁻¹.^[36] Based on a long-term experiment, Sharma et al.^[37] reported that the conjunctive use of urea and organics such as loppings of *Leucaena* and *Gliricidia* (1:1 ratio

on N equivalent) increased sorghum grain yield to 1.69–1.72 Mg ha⁻¹, respectively, and thus revealed that a minimum of 50% N requirement of sorghum can be easily met from farm-based organic sources. This research information can be used to supplement fertilizer N up to 50% by using green loppings of *Gliricidia maculata* and *Leucaena leucocephala* and will be useful while planning for the cultivation of organic produce. Furthermore, the SOC concentration was significantly increased by the application of crop residues such as sorghum stover and *Gliricidia* at the rate of 2 Mg ha⁻¹ under minimum and conventional tillage systems for rainfed sorghum–castor rotation on Alfisols.^[37]

CONCLUSION

SOC is a strong determinant of soil quality, which ultimately plays a pivotal role in maintaining productivity on a sustainable basis. It is more important in arid and semiarid conditions as the soils under these conditions are deficient in many nutrients. Carbon storage in the soil profile not only improves fertility but also abates global warming. SOC stocks in soil profiles across India showed wide variations and followed the order Vertisols > Inceptisols > Alfisols > Aridisols. Data from experiments involving long-term cropping, fertilization, and manuring show that mineral fertilizer application alone can neither sustain the productivity nor maintain the SOC stock. The depletion of organic C occurs without organics irrespective of production system and soil type. Application of organics along with mineral fertilizer can sustain productivity and sequester significant amount of soil C. The rate of depletion of SOC is in the range from 0.15 Mg C ha⁻¹ yr⁻¹ in rice-based system to 0.92 Mg C ha⁻¹ yr⁻¹ in groundnut–finger millet system. To curtail this depletion, C input of 1.10–3.47 Mg C ha⁻¹ yr⁻¹ is required as a maintenance dose, depending on soil type, ecoregion, and land use. There are many changes in agricultural management practices, which have positive impacts on SOC. Large scope exists in the adoption of C-positive management practices at farm level. In particular, reduction in tillage and retention of organic residues play key role in improving soil structure and hydrological properties as well as maintaining or increasing yields. Practices such as legume cover crops, vermicompost, tank silt application, crop residue recycling through mulching and compost, green leaf manuring, integrated nutrient management and site-specific nutrient management along with soil water conservation measures, and integrated farming systems are some of the high priority technologies for maintaining soil health and enhancing C sequestration in rainfed ecosystems in India.

RESEARCH AND POLICY NEEDS

There is a need to launch long-term field experiments to quantify the influence of best management practices

on the soil carbon sequestration in various ecosystems and crop production systems.

There is a need for refinement of the existing data on critical C input requirement as well as to derive this type of data set for other crop production systems in diverse soil types.

Quantification is required for C stabilization (%) from different types of residues and organic manures.

Monitoring and verification of the rate of SOC sequestration in a transparent, cost-effective, and credible manner are key requirement for developing a user-friendly carbon trading system.

Quantification of the country's soil carbon sequestration potential in terms of various land use and management scenarios using soil carbon models.

Information on the recommended land use and management practices for soil C sequestration and corresponding rates under "on-farm" conditions.

Carbon Sequestration: Urban Ecosystems

Adam Louis Selhorst

Environmental Studies, Ashford University, San Diego, California, U.S.A.

Abstract

As global climate change (GCC) continues to be an international concern, researchers are looking at the potential of urban soils to sequester atmospheric carbon (C). With the rapid expansion of global urbanization, the subsequent development of urban green space may prove to be a vital C sink. Urban turfgrass systems have shown the ability to sequester C at rates of 0.69–3.58 Mg C ha⁻¹ yr⁻¹, providing an overall potential sink capacity of 20.8–96.3 Mg C ha⁻¹. However, sequestration potential is dependent on climatic properties with optimal soil organic carbon (SOC) pools located in cooler regions with precipitation levels between 60 and 70 cm yr⁻¹. Furthermore, soil physical properties also influence SOC sequestration as sink capacity is positively correlated with increases in bulk density (ρ_b) up to 1.5 Mg m⁻³ and increased soil nitrogen concentrations. However, the hidden carbon costs (HCCs) due to urban soil management practices result in emissions of 189 kg carbon equivalent (Ce) ha⁻¹ yr⁻¹ for mowing practices and 63.6 kg Ce ha⁻¹ yr⁻¹ for fertilization application in home lawns. In more intensively managed soils such as golf courses, HCCs accounted for as much as 302 kg Ce ha⁻¹ yr⁻¹. Thus, HCCs converted home lawn soils from sinks to sources in 66–199 years, depending on management intensity. In order to maximize the potential of urban soils to sequester C, low C-intensive management practices should be utilized to maintain ideal soil physical properties in regions with optimal climatic conditions.

INTRODUCTION

As rapid expansion of the human population continues, both urbanization and industrialization have increased globally. These increases have been coupled with significant alterations in worldwide land use and a growing combustion of fossil fuels. Such changes have resulted in the anthropogenic enrichment in atmospheric carbon dioxide (CO₂), leading to a host of environmental concerns, most notably global climate change (GCC). In an effort to slow the increase in atmospheric carbon (C) enrichment, researchers are beginning to note the potential of urban soils to sequester C and mitigate the effects of GCC.

With the migration of global populations moving toward city centers, urban soils are becoming an increasingly important part of the landscape. The enhancement of green space is seen as highly desirable, often coming in the form of parks, athletic fields, golf courses, and home lawns. While providing recreational and aesthetic benefits, much research has shown the potential of urban soils to sequester large amounts of C. However, the extent of sequestration may be affected by climatic factors, soil properties, and turf management regimes. This entry examines the past and ongoing research on the ability of urban soils to sequester C. Additionally, it reviews the impacts of temperature, precipitation, and various soil properties on sequestration potential and views all results in light of the various hidden carbon costs (HCCs) that are often generated due to turfgrass maintenance practices.

C SEQUESTRATION POTENTIAL IN URBAN SOILS

As the global population continues to trend upward, urban areas are occupying an increasingly large portion of the world's landscape. Urban land is increasing twice as fast as population, and it is estimated that by 2030 land dedicated for urban use will be triple 2000 levels, increasing by as much as 1.2×10^6 km².^[1] Such prolific land use change has led to global concerns regarding the negative environmental impacts associated with rapid urbanization including its contribution to GCC.

Urbanization and its subsequent land use change have shown the ability to alter the C dynamics within a system. Globally, soils hold an estimated C of 2500 Pg; however, significant perturbations can lead to the depletion of soil organic matter pools, resulting in the direct release of soil organic carbon (SOC) into the atmosphere in the form of CO₂.^[2] Although there is concern over the loss of SOC to the atmosphere, formerly disturbed soils provide an immense opportunity to resequester a large portion of previously emitted SOC and thus might prove to be an effective tool in GCC mitigation. Each year, 120 Pg of C is released to the atmosphere by soil and plant respiration. If 10% of this C could be retained within soils, it could offset the growing C emissions released through fossil fuel burning.^[2] Thus, soils have the potential to sequester C and reduce the rate of atmospheric CO₂ enrichment.

Urban soils may be of particular interest due to the growing area of green space being utilized by city planners. As they are areas of high productivity, green areas have been shown to function as C sinks.^[3] Research has illustrated how unproductive soils can provide long-term C sequestration potential upon conversion to grasslands with C turnover rates as high as 2200 years.^[4] Additionally, studies throughout the world have confirmed that reversion of C-depleted cropland to grasslands can result in soil C sequestration at rates between 0.86 and 1.11 Mg C ha⁻¹ yr⁻¹^[4–6] (Table 1).

While reversion of depleted soils to prior land use does show significant sequestration potential, urban soils contain higher concentrations of SOC than their suburban counterparts.^[14] In general, this is due to the intensive management and subsequent high productivity of turfgrasses maintained in urban settings. Golf courses provide an example of one of the most intensively managed urban soils. The proliferation of highly productive grasses and the regular fertilization and irrigation they receive allow newly designed courses to sequester C for between 20 and 90 years at rates between 0.15 and 3.58 Mg C ha⁻¹ yr⁻¹ depending on original land use.^[8–12] This means that a golf course constructed on previously depleted cropland has the potential to sequester as much as 3517 Mg of C.^[13]

While golf course area comprises a small component of urban soil land use, turf proliferation in the form of parks and commercial and residential lawns may provide a more representative sample of the ability of urban soils to sequester SOC. Research indicates that home lawns can sequester C at rates between 0.9 C ha⁻¹ yr⁻¹ and 5.4 Mg C ha⁻¹ yr⁻¹.^[13]

Additionally, total sequestration potential has been measured at as much as 144 Mg C ha⁻¹, depending on management intensity and soil location.^[15] Overall, home lawns throughout the United States hold the potential to harness as much as 496.3 Tg of C.^[13]

In addition to the direct sequestration of C due to turfgrass establishment, urban soils may provide secondary benefits allowing for the additional sequestration of C. First, soil erosion is responsible for a loss of SOC. Establishment of turf on areas highly susceptible to erosion may prevent such loss and lead to the retention of soil C in urban areas. Furthermore, the incorporation of trees and other foliage into urban green space plans may provide another venue for the sequestration of C as plants have illustrated the potential to act as C sinks.^[16] More specifically, tree biomass has been shown to accumulate C at a rate of 1.7 Mg C ha⁻¹ yr⁻¹ in urban parks accounting for as much as 45.9 Mg C ha⁻¹.^[17] It is also important to note that mulched areas have shown the ability to increase both SOC content and microbial biomass activity leading to SOC concentrations on par and in many cases higher than in neighboring turf areas.^[18] Thus, when possible, mulching of urban soils may prove to be a valid sequestration strategy. Thus, the incorporation of a mixture of plants, mulched areas, and grasses into the urban landscape may provide an optimal C sequestration strategy for urban soils.

Finally, it is important to note that all data presented here reference turf soils that are managed with minimal disruption to the soil structure. This is an important distinction as regularly resurfaced turfgrass systems such as athletic fields have shown no C sequestration benefits due to the regular removal of topsoil, aboveground and belowground biomass, and mixing of soil structure.^[19] As such, to maximize the C sequestration potential in urban soils, management practices must be cautious to avoid significant disturbances to the soil structure in order to evade the unintentional release of SOC to the atmosphere.

CLIMATIC EFFECTS ON C SEQUESTRATION IN URBAN SOILS

While urban soils have shown the ability to enhance the global C pool, the extent of their sequestration potential may be affected by climatic conditions. While past research has shown both positive and negative interactions between mean annual temperature (MAT) and soil C concentration rates, research in home lawn systems has shown a direct correlation between lower temperatures and higher SOC pools (Fig. 1).^[20] This is most likely due to decreased plant growth at higher temperatures coupled with increased SOC decomposition rates in response to enhanced microbial activity.^[21] Along with decreased net photosynthetic rates at temperatures greater than 30°C,^[22] elevated MAT is associated with decreased root development and overall turf quality in grass systems.^[23]

Fig. 1 Mean soil organic carbon pool for U.S. home lawns located in various mean annual temperatures following initial soil organic carbon sequestration to a depth of 15 cm (analysis of variance for interaction of soil organic carbon pool and mean annual temperature: $p < 0.001$, degrees of freedom (DF) = 341, $N = 342$).

Moisture content can also alter soil-based C as mean annual precipitation (MAP) has been shown to affect SOC concentrations. In dry climates, the lack of vegetation can limit soil C storage; thus, increased MAP in dry areas has shown the ability to enhance SOC pools.^[24] However, research illustrates that continued soil saturation can lead to inhibition of SOC storage, and lower overall C concentrations are found in saturated climates.^[25] Analysis of urban soils under home lawn management has shown highest levels of SOC concentration in climates where precipitation levels are between 60 cm yr⁻¹ and

70 cm yr⁻¹ (Fig. 2).^[20] These findings may provide justification for the addition of irrigation water in dry climates and the avoidance of supplemental watering in wetter climates. However, grass species type may also play a vital role in determining the optimal moisture level for turf quality and SOC sequestration. Home lawns seeded with drought-tolerant species such as St. Augustine and Bermuda grass may ultimately require lower levels of irrigation, while less tolerant species such as Zoysiagrass may require greater application of supplemental water.^[26]

Fig. 2 Mean soil organic carbon pool for U.S. home lawns located in various mean annual precipitations following initial soil organic carbon sequestration to a depth of 15 cm (analysis of variance for interaction of soil organic carbon pool and mean annual temperature: $p < 0.001$, DF = 350, $N = 351$).

Based on the research presented, maximization of the C sequestration potential of urban soils under turfgrass management may be obtained by considering the climatic conditions during urban planning. In extremely arid and hot climates, the use of mulched soils with drought-tolerant foliage may provide a better alternative to turfgrasses that will require ample irrigation and minimal sequestration benefits. However, for soils located in cooler climates with moderate MAP levels, expansion of turfed areas may prove to be an effective method of enhancing the overall SOC pool and maximizing the potential benefits of urban soils.

INFLUENCE OF SOIL PROPERTIES ON C SEQUESTRATION IN URBAN SOILS

In conjunction with climatic factors, soil properties can also greatly influence the ability of urban soils to sequester C. Conversion of land from natural to urban uses can either increase or decrease C storage due to changes in the

soil properties and structure. One important property associated with C sequestration in urban ecosystems is bulk density (ρ_b). In general, urban soils show high levels of soil compaction and thus have elevated bulk densities.^[27] This compaction has been shown to decrease SOC content through limiting of fresh organic matter inputs into lower levels of the soil profile.^[27] However, this does provide an opportunity for enhancing the SOC sequestration potential of urban soils as maintenance practices that result in a decrease in compaction can enhance the soils' ability to sequester C. Furthermore, research has shown optimal levels of C sequestration in urban home lawns when ρ_b is maintained between 1.4 Mg m^{-3} and 1.5 Mg m^{-3} (Fig. 3).^[20] Thus, maintenance of turfgrass systems directed at optimal compaction could enhance the ability of urban soil to sequester C.

In addition to ρ_b , clay content and pH may also alter the sequestration potential in urban soils. Fine soils with elevated levels of silt + clay have been shown in certain conditions to result in increased SOC pools.^[28] However, with

Fig. 3 The effect of soil bulk density, clay + silt content, pH, and nitrogen on the mean soil organic carbon pool for U.S. home lawns following initial soil organic carbon sequestration to a depth of 15 cm [analysis of variance (ANOVA) for interaction of soil organic carbon pool and soil bulk density: $p < 0.001$, $DF = 341$, $N = 342$; ANOVA for interaction of soil organic carbon pool and soil clay + silt content: $p = 0.237$, $DF = 341$, $N = 342$; ANOVA for interaction of soil organic carbon pool and soil pH: $p = 0.410$, $DF = 341$, $N = 342$; ANOVA for interaction of soil organic carbon pool and soil nitrogen: $p < 0.001$, $DF = 340$, $N = 341$].

proper moisture, coarse particles can account for as much as 40% of the SOC.^[29] Additionally, pH has been shown to alter microbial communities which are responsible for the decomposition of biomass, which can have substantial effects on SOC pools.^[28] However, research conducted nationwide on home lawns showed no correlation between either soil texture or pH and SOC sequestration ability (Fig. 3).^[20] Thus, texture and pH levels may have little overall effect on the ability of urban soils under turfgrass regimes to sequester atmospheric C.

Alternatively, research into soil nitrogen (N) concentrations did show a significant effect on SOC content with each 0.1% increase in N content leading to a 0.99% increase in SOC (Fig. 3).^[20] Increased N levels have been shown to decrease litter decomposition, leading to enhanced overall C pools.^[30] This is especially important to note in highly managed urban turfgrass systems as the addition of N fertilizer can greatly enhance SOC sequestration potential. In terrestrial ecosystems, anthropogenic N can increase SOC pools at rates as much as 0.1–0.3 Pg C yr⁻¹.^[31] Based on these findings, proper management strategies may include the regular addition of inorganic N to maintain optimal turfgrass decomposition rates to maximize soil C sequestration potential.

HIDDEN COSTS OF URBAN SOIL MANAGEMENT

The bulk of this entry has reviewed the high potential of turf-covered urban soils to sequester C; however, results must be viewed in light of the HCCs due to turf and soil maintenance. Although increased turf management practices can directly lead to enhanced soil C sequestration, the emissions produced through these management practices must be considered when determining the overall potential of urban turfgrass soils to sequester C. Additionally, management due to mowing and the application of fertilizer, pesticides, insecticides, and irrigation can be both time-consuming and financially costly for a landowner. For these reasons, the continued use of fossil fuels and chemicals to maintain healthy looking turfgrasses may negate much of the enhanced sequestration potential of urban soils.

The addition of artificial chemicals has shown the ability to enhance soil and turf health in urban ecosystems; however, the emissions created through their use must be weighed against the benefits provided. For each 1 kg of fertilizer added to turf, 0.1–0.8 kg of carbon equivalent (Ce) is released into the atmosphere. Emissions for insecticides and fungicides are even greater, releasing 1.2–12.6 kg Ce for each 1 kg of active ingredient.^[32] For intensively managed systems such as golf courses, this can lead to significant atmospheric emissions ranging from 0.64 kg Ce ha⁻¹ for insecticides to 32.03 kg Ce ha⁻¹ for N-based fertilizers (Table 2).^[12] Thus, highly managed green spaces

Table 2 Total carbon emissions per hectare for golf course maintenance practices.

Emission source	Total emissions (kg Ce ha ⁻¹)
Unleaded fuel	77.36
Diesel fuel	140.20
Irrigation	13.38
Insecticide	0.64
Herbicide	4.40
Fungicide	29.44
Nitrogen fertilizer	32.03
Phosphorous fertilizer	2.05
Potassium fertilizer	2.95
Total Emissions	302.44

such as golf courses may not provide the most efficient strategy for the sequestration of atmospheric C.

Due to the decreased HCCs and higher proportion of land area, less intensively managed urban turf soils may provide a more efficient means of sequestering atmospheric C. For home lawns, emissions due to fertilization at the industry-recommended rate account for an average annual emission of 63.6 kg Ce ha⁻¹ yr⁻¹ (Fig. 4).^[13] Although much lower than in golf systems, this represents a significant annual output of C due to management practices. Additionally, secondary nitrous oxide (N₂O) emissions from such areas due to fertilization are significantly elevated, releasing as much as 0.1–0.3 g m⁻² yr⁻¹.^[19] This is especially important to note, as N₂O is a greenhouse gas with a global warming potential 310 times greater than that of CO₂.

In addition to supplemental chemical use, regular mowing of turfgrasses with fossil fuel generated equipment can further limit the net sequestration potential of some urban soils. For each 1 kg of fuel burned, 0.85 kg Ce is emitted into the atmosphere.^[33] For golf courses that utilize regular

Fig. 4 Carbon emissions due to home lawn turf maintenance practices.

daily mowing and other fossil fuel burning equipment as part of their management practices, this can account for as much as 217.56 kg Ce ha⁻¹ yr⁻¹ (Table 2).^[12] Again, such emissions are greatly reduced for soils maintained for home lawn use with emissions due to mowing accounting for an estimated 189.7 kg Ce ha⁻¹ yr⁻¹ (Fig. 4).^[13]

Furthermore, irrigation emissions are common in urban ecosystems, especially in dry climates. In these areas, excess emissions are produced due to the pumping of water and other environmental concerns during periods of water shortage. For intensively managed systems such as golf courses, supplemental water usage can account for as much as 13.38 kg Ce ha⁻¹ (Table 2).^[12] Furthermore, the installation of irrigation equipment can release as much as 121 kg Ce ha⁻¹ due to fossil fuel burning^[34] and might provide additional concerns as installation often disrupts the soil profile and can lead to the release of previously sequestered SOC.

Additional secondary environmental concerns may further lessen the positive impact of increased C sequestration in urban soils. It has been observed that the majority of urban turfgrass systems have become contaminated through the use of chemical additions. Up to 53% of the N fertilizer added to turfgrasses is lost as surface runoff,^[35] and 15% of all pesticides found in groundwater leached from home lawns.^[36] Not only does the loss of these chemicals from the soil lead to negative environmental externalities, but also to increased cost for the homeowner and the community.

Accounting for the emissions generated due to fossil fuel use, application of maintenance chemicals, and supplemental water use through irrigation, the net C sequestration potential of urban soils is greatly reduced. For intensively managed turfgrass soils such as golf courses, the significant emissions produced shift courses from sinks to sources just 30 years post-establishment, thus limiting the overall potential of the these soils to mitigate GCC.^[23] However, due to the increased acreage and reduced management emissions, less intensively maintained systems provide a greater potential to mitigate the increased rate of atmospheric C enrichment.

Based on the available data, combined U.S. home lawn acreage has a C sink capacity of 496.3 Tg of C (Table 3).^[13] However, in order to determine the GCC mitigation potential of these soils, C emitted to the atmosphere through management practices is subtracted from the total sink capacity to determine the net C sequestration potential. While maintenance emissions are significantly lower for home lawns than for golf systems, lawn soils emit between 2.5 and 7.55 Tg Ce yr⁻¹ (low vs. high lawn management strategies; Table 3). Taking into account the C sink capacity and standard maintenance emissions, home lawns throughout the United States illustrate a potential to act as sinks for 66–199 years before shifting to sources. If fossil-fuel-based mowing emissions are removed, C sink time could be significantly lengthened to 130–775 years (Table 3).

Table 3 Potential organic carbon sink capacity, hidden carbon costs (HCCs) due to maintenance emissions, and time for sequestration potential to be negated by emissions for U.S. home lawn soils under various maintenance regimes.

Management intensity	Potential soil organic carbon sink capacity (Tg C)	HCCs of maintenance emissions (Tg Ce yr ⁻¹)	Time until sequestration = emissions (years)
Standard	496.3	2.50–7.55	66–199
Mowing only	496.3	1.87–3.74	133–265
Fertilization only	496.3	0.64–3.81	130–775

While this is impractical in many cases, large quantities of home lawns throughout the United States are small enough to utilize non-fossil-fuel-based rotary mowers. Additionally, developments of solar-generated mowing equipment could allow for a large-scale reduction in mowing emissions. It is important to note, however, that these values refer to the sequestration potential of newly established home lawns. Over time, turfgrass soils become C saturated and no longer illustrate the potential to sequester C within the soil. As many home lawns have been established for some time, their potential to sequester C may be partially or entirely eliminated, thus lowering the total potential C sink capacity reported.

In order to maximize the potential of urban soils to sequester C, a low management regime is suggested. This would consist of fertilizer and other chemical application at the minimum rate necessary to sustain a healthy lawn. Excess application results in emissions, runoff, and leaching of chemicals into groundwater. Additionally, proper irrigation strategies that utilize supplemental water application only when necessary limit pumping emissions, N₂O production, and excessive water use. Furthermore, avoidance of mowing can reduce fossil fuel use and in many cases increase root stability and turf health. This could result in decreased emissions coupled with an increase in the C sequestration potential of the soil. Finally, the establishment of turfgrasses in areas that require high water and/or chemical demands should be avoided. Extremely arid soils may benefit more from the incorporation of xeriscapes or through the establishment of drought-tolerant plant species with mulching incorporated than from the establishment of home lawns or urban parks. Quality land management practices and urban design can serve to maximize the potential benefits of urban soils while reducing the impending drawbacks.

CONCLUSION

Examination of global research findings illustrates a clear ability of urban soils to sequester atmospheric C. Additionally, the establishment of turfgrasses on such soils may

successfully enhance the C sequestration potential of urban ecosystems. This potential may be enriched or hindered based on the climatic and soil properties of the site. Turf-grasses established in cooler climates with moderate rainfall may provide optimal conditions for soil C sequestration. Establishment of grasses on soils with a p_b of 1.45–1.55 Mg m⁻³ and sufficient levels of soil N may further bolster the soil's potential to sequester C. As such, the ability of urban soils to sequester C may be maximized by maintaining soil properties in the desired ranges and focusing urban turfgrass development in regions with optimal climates.

Based upon the research reviewed in this entry, the establishment of green space through the use of urban parks and the planting of home lawns could provide a sink for excess atmospheric C. However, sequestration potential must be weighed against the HCCs generated through turfgrass maintenance practices. While newly established urban turfgrasses are likely to sequester C for a period of time, the continued mowing and C-intensive fertilization of these turfs may negate all of the sequestration benefits. As such, urban green space should be maximized in areas with optimal climatic conditions and in areas where soil properties are ideal for C sequestration. Additionally, a research aimed at determining the optimal level of maintenance necessary to maximize sequestration potential while minimizing the HCCs could prove vital. With such information, turf managers and homeowners alike could utilize research-generated best practices in order to maximize the ability of urban soils to mitigate GCC.

ACKNOWLEDGMENTS

This entry is based in part on work done for the completion of the PhD in Environmental Science from The Ohio State University. As such, I would like to thank The Ohio State University and the Environmental Science Graduate Program for their financial and academic support. Additionally, I would like to express my gratitude to Scotts Lawn Service for providing additional funding and advice throughout the program. Carbon Sink Capacity: Soil Profile Characteristics

Yuri Lopes Zinn

Federal University of Lavras, Lavras, Brazil

Abstract

Soils are increasingly considered as viable, effective carbon (C) sinks that play a major role in the global C cycle. Most research work on this issue focused on the effect of external factors such as climate, soil management, and vegetation on soil C sink capacity, whereas the influence of the soil profile characteristics has been generally overlooked. This entry reviews how soil organic carbon (SOC) and soil inorganic carbon (SIC) sink capacities are affected by a soil's inherent properties. The role of soil structure, particle size distribution, clay mineralogy, and depth on SOC retention was reviewed, whereas soil pH and base cation availability were discussed in regard to their control on SIC sink capacity.

INTRODUCTION

Increasing concern about global warming due to anthropogenic carbon dioxide (CO₂) emissions to the atmosphere has raised interest on soils as potential carbon (C) sinks. In fact, soils of the world store C in amounts higher than those in biomass or the atmosphere, although lower than those in geological deposits.^[1] In soils, C is stored either as soil organic carbon (SOC) or as soil inorganic carbon (SIC). The turnover times for both forms are generally much shorter than those for hydrocarbons or carbonates of sedimentary rocks, but on the other hand, they are longer than those for C stored in plant biomass. In other words, soils are not the largest C pool on earth, but they represent a C sink capacity that can be achieved relatively faster and at lower costs than geological pools and in more stable forms than those in wood or forest biomass. A great deal of research has been conducted on how environmental or external factors such as climate, vegetation, and management affect the retention of C, especially as SOC.^[2,3] This entry presents a brief review on a different perspective, i.e., on which and how soil internal factors, or profile characteristics, affect soil C sink capacity.

SOC SINK CAPACITY

The cycling of dead organic matter is one of the main ecological services provided by soils, releasing mineral nutrients to plants during the decomposition of those residues. This is a complex process that encompasses numerous decomposition reactions and rates^[3] for each organic functional group and decomposer organism, with turnover times ranging from hours to centuries or even millennia. Furthermore, a fast, full mineralization to CO₂ is common only for the simplest organic compounds, and partial

decay of large macromolecules such as cellulose and lignins constantly produces intermediate compounds, in a process called humification.^[3] These by-products are the highly altered humic substances, comprise ca. 2–20% of the original C input,^[1] and are stored in soils altogether with fresh solid residues and smaller, more soluble intermediates. This mix of compounds varies widely in particle or molecular size, in surface or charge properties, and in their affinity for water, resulting in the inherently intricate nature of SOC. In consequence, it follows that different SOC components are stored in different soil compartments, by means of various mechanisms, which depend on the soil profile characteristics described in the following sections.

Soil Structure

SOC concentration is determined in fine earth samples, excluding materials >2 mm. The coarsest (sand-sized) components of SOC chiefly consist of fresh or slightly altered plant debris, although partially burnt and old, recalcitrant materials also often occur. These materials are commonly named as particulate organic matter (POM) and can exist either occluded within soil aggregates or interspersed among the aggregates (“free” POM).^[4] Soil aggregates are the secondary particles built up by primary (sand, silt, and clay) particles and SOC, in different shapes and sizes, which compose soil structure.^[5] The occlusion of POM within aggregates is a process that slows down its decomposition by reducing aeration and access to decomposers, leading to slower turnover^[4] and a general perception that soils with a higher degree of aggregation store more SOC. In fact, one of the main reasons why soils are tilled is to promote SOC decomposition and release nutrients to crops,^[6] an effect ascribed to the disruption of

aggregates, enhancing oxygenation and exposing labile POM to decomposers. This is the main reason why continuous annual plowing often leads to SOC depletion, in comparison with no-till farming.^[5] By the same token, a positive feedback between SOC sink capacity and soil structure exists,^[7] which can be seen as an improvement in soil aggregate stability as SOC levels increase.

It is difficult to ascribe precisely how much POM–SOC is actually free or occluded, because: 1) sieving samples <2 mm releases POM originally occluded within large macroaggregates; 2) aggregate size distribution changes seasonally and with cultivation practices; 3) measurement protocols, commonly based on density separation or particle size fractionations, vary widely in the literature, making interstudies comparison difficult. However, there is evidence that most POM in forest or native soils occurs actually outside aggregates (Fig. 1), but with continuous cultivation, this situation is reversed as most free POM rapidly decays.^[4] It can be generally expected that, for the same climate and drainage conditions, soils with more water-stable aggregates will hold more bulk SOC than those with less stable aggregation or smaller aggregates,^[5] although this effect may be restricted to surface layers where aggregation factors (e.g., wetting–drying cycles and soil fauna) are more active.^[7]

Fig. 1 Surface horizon of a gibbsitic Oxisol under native savanna vegetation in Brazil. Most POM occurs as roots (R) in the voids (V) among the granular structure, i.e., outside aggregates, although a charcoal (C) fragment can be seen occluded within an aggregate. The root-like feature in the upper center is actually a gibbsite nodule (N). Although this soil has a total organic carbon content of 4%, it has a light reddish color due to the significant presence of Fe and Al oxides masking the dark color otherwise expected for soils with such high C concentrations.

Soil Particle Size Distribution

In well-drained soils of many parts of the world, SOC concentrations are highly correlated with the concentrations of soil particles of size smaller than clay (2 μm) or silt (20 or 50 μm). This effect has been ascribed to various mechanisms, including inactivation of SOC-oxidizing enzymes, greater water retention leading to higher plant biomass and C inputs, stronger aggregation, and more cation bridges between SOC and clays.^[3,8] However, since the clay content of a soil strongly controls its specific surface area, it is more likely that the major mechanism involved in this textural control is the greater availability of mineral surfaces able to sorb soluble and colloidal SOC, in soils of finer textures.^[8] In fact, when different textured soils have their particle size fractions separated and analyzed, the higher SOC sink capacity in the finer soils can be ascribed to larger C pools in the clay size, whereas the sand and silt size C pools vary little with soil texture.^[8] This trend demonstrates that the main effect of higher clay contents is the stabilization^[3] of soluble and colloidal SOC by sorptive effects and has the critical consequence that the clay fraction generally holds more of the total SOC than the silt and sand fractions. Soil structure has an indirect effect on this textural control, as a higher degree of clay flocculation and cementation is likely to improve SOC stabilization.

Clay Mineralogy

A direct consequence of the sorption-based textural control described above is that the nature of clay minerals and their surfaces strongly affect SOC sink capacity. A general rule states that the smaller the size of the crystals, the higher the specific surface area and the higher the potential for sorption. Thus, amorphous silicon, aluminum (Al), and iron (Fe) phases common in Andisols and Spodosols favor SOC sequestration^[3] in comparison with well-crystallized clay minerals with lower surface areas. However, there is a large variability in terms of surface properties, specific area, and charge density, not only among the different clay mineral types but also for different provenances of the same mineral. Studies on sorption of dissolved organic C by clays are many, but just like those on soil structure, a comprehensive understanding is hindered by non-standardization of analytical procedures and disparate experimental conditions. Nevertheless, it is evident that highly active smectite clays are more efficient than kaolinite in sorbing SOC when sorption results are expressed on a mass basis, but when calculated in a specific surface area basis, kaolinite is more effective than smectites, perhaps due to its Al–OH surfaces.^[9] There is also evidence of an even greater SOC affinity to crystalline Fe oxides such as goethite; since in some cases, SOC and Fe dithionite concentrations show even higher correlation than with clay + silt.^[8] This effect is not restricted to aerobic soils, having been reported that Fe oxides respond for ca. 20% of total organic C retention

in oceanic sediments.^[10] Goethite is known to greatly increase SOC sorption to kaolinite and to decrease its desorption, but this effect is null for smectites and illites,^[9] which may suggest that kaolinitic, Fe-rich tropical soils have a high C sink capacity. In addition, an indirect effect of clay mineralogy (and texture) on SOC sink capacity can be exerted through aggregation, which is more stable in soils rich in Fe and Al oxides.^[5,7] In such soils, even high concentrations of SOC have little or no darkening effect on the soil color (Fig. 1), which in Fe-poor soils of temperate regions generally result in black colors.

Soil Depth and Bulk Density

Soil sampling in subsurface depths has always been limited in SOC studies,^[8] which is not only due to procedural difficulties but also due to a general expectancy that changes in SOC are restricted to the soil surface. Soil depth is a profile characteristic that influences SOC sink capacity in at least two ways, the most obvious being that deeper soils provide more mineral surfaces to sorb SOC than shallow soils. SOC can reach deeper layers by root colonization and activity, but especially by downward flow of dissolved SOC less strongly bound to soil minerals.^[11] This effect is not restricted to A and B horizons, since C horizons have very low SOC concentrations (<0.1%) but can be so deep and dense that total SOC stocks can reach 300 Mg ha⁻¹ in >30 m deep profiles, even under relatively dry Mediterranean climate.^[12] The downward migration of SOC also defines the spodic and sombric horizons, and although these features are not causally ascribed to depth as a factor per se, their location often below 1 m is another example of how depth can influence SOC stocks in regional estimates and actual C sink capacity.

Soil depth apparently also affects SOC sink capacity by determining how deep and thoroughly SOC can migrate downward and thus be removed from topsoil giving an erroneous idea of lower C sink capacity. This effect is also determined by soil bulk density and structure patterns. In the humid tropics, very deep, highly porous soils such as Oxisols with granular structure often have lower SOC concentrations in topsoil in comparison with shallower, more dense Ultisols and Inceptisols. However, in the latter soils, SOC concentrations tend to decrease sharply with depth, whereas in Oxisols such decrease is less evident and concentrations of 1% at a depth of 2 m are not uncommon.^[13] More research is needed on this effect of depth, including not only deep samplings but also a mathematical analysis and modeling of involved factors and their impact on SOC stratification.

SIC SINK CAPACITY

In this text, SIC refers only to carbonate minerals generated in soil environments, i.e., excluding those present within

soils but inherited from calcareous parent materials upon weathering. Due to its synthesis (and resynthesis), SIC is often of a much finer grain size than inherited carbonates, and quantitative assessments of how much carbonate-C is actually pedogenic are difficult and involve microscopic or isotopic techniques.^[14,15] It has been estimated that SIC is sequestered at rates of 0.005–0.15 Mg ha⁻¹ yr⁻¹, i.e., much slower than 0.1–1.0 Mg ha⁻¹ yr⁻¹ attributed to SOC.^[1] In addition, ca. 950 Pg of SIC is stored in soils of the world, to a depth of 1 m,^[1] a figure that comprises only two-thirds of the amounts estimated to be stored as SOC. Nevertheless, SIC is relevant as a C sink since its occurrence is favored in the semiarid and arid lands that occupy ca. 37% of the earth's land surface.^[14] Semiarid or drier climatic regimes are generally associated with the two soil profile characteristics that allow for the genesis and stability of SIC, i.e., the existence of near-neutral to alkaline pH and the availability of basic cations.

Neutral and Alkaline pH

The principal reactions involving carbonates in soils are well known,^[16] but since they are multiple and cannot be treated in detail here, they are summarized as follows:^[14,15]

This reversible reaction basically shows that calcite, the main calcium carbonate in soils and rocks, dissolves due to the acidity (H⁺) generated by dissociation of carbonic acid, a weak acid, formed by the subreaction between CO₂ and H₂O (carbonation). In addition, the equation shows that the dissolved ions can precipitate again in the soil by desiccation and that increasing humidity and CO₂ pressure promote carbonate dissolution. Moisture also has the indirect, longer term effect of promoting plant growth and thus the formation of various organic acids and humic substances that protonate and dissolve carbonates. The equilibrium of the reaction varies swiftly with Ca²⁺, water, and CO₂ concentrations as well as with interference of factors such as dissolved organic C and other ions, so it is quite difficult to discern when carbonates are forming or dissolving in net terms.^[16] However, in the long term, SIC is formed and is relatively stable at slightly alkaline soil conditions (pH > 7.2) and is not expected in soils with pH values <6.5. As a consequence, SIC occurs in Aridisols, Mollisols, Vertisols, and some Alfisols but not in acidic soils such as Oxisols, Ultisols, and Histosols.

Base Cations Availability

As noted in the equation above, base cations (especially Ca²⁺, but also Mg²⁺, Na⁺, K⁺, and Fe²⁺)^[15] are required either dissolved or sorbed by clay surfaces in order to precipitate SIC with CO₂-rich soil solutions. To promote net SIC sequestration, these cations must come from sources

other than dissolution of preexisting carbonates. Deposition of gypsum dust and Ca^{2+} -laden rainwater can be important,^[17] but the weathering of silicate minerals (e.g., feldspars, micas, amphiboles, pyroxenes, and olivines), which form the bulk of earth's crustal rocks, release most of these cations. In semiarid or drier regions where bedrock is comprised of basic to intermediate rocks, these minerals can be abundant in soils as sand and silt grains. After the infrequent rain events, such grains undergo chemical weathering, mostly by hydrolysis with the H^+ produced by carbonation, and base cations are released in solution. Upon evaporation, these cations precipitate with the HCO_3^- and CO_3^{2-} ions, mostly forming fine-grained calcite, magnesium–calcite, and others on and near partially weathered silicate grains, easily visible in soil thin sections.^[16] Alkaline dissolution of silicates in contact with these carbonates in soils is visible as serrated grain surfaces,^[16] which further accelerates cation release and carbonate precipitation. The multiplication and growth of SIC crystals promote cementation of soil aggregates and layers (caliches, calcretes, “k” horizons, etc.),^[17] implying that, unlike SOC, SIC sequestration may not increase soil quality since it can restrict root development. Due to the inherent low contents of clay minerals and Fe/Al oxides in semiarid or drier soils, there is little apparent effect of soil texture, mineralogy, and structure on SIC sequestration, as is the case for SOC sequestration.

CONCLUSION

The main soil profile characteristics affecting the C sink capacity either as organic or as inorganic compounds are reviewed and interpreted envisaging a novel understanding on how soil C dynamics can be managed. However, such initiatives are complicated by lack of standard analytical procedures, by insufficient sampling depth, and by mutual, indirect effects of all profile characteristics on the C retention mechanism of each other. The research on soils as sinks or sources of C must provide improved, thorough soil characterization in order to better provide insights into how profile characteristics interact with external controls of C retention, such as climate and site management. It is also recommended that the C sink capacity of charcoal within the soil matrix (Fig. 1) be studied with regard to whether and how it is affected by those profile characteristics.

Carbon: Inelastic Neutron Scattering

Lucian Wielopolski

Environmental Sciences Department, Brookhaven National Laboratory, Upton,
New York, U.S.A.

Abstract

The growing importance of accurately determining soil carbon (C) is attributable to several factors concerning the quality and fertility of soil and to society's emerging need to broker C sequestration via soil C credits under the U.S. Department of Energy's Voluntary Greenhouse Gas Reporting Program, established by section 1605(b) of the Energy Policy Act of 1992. Thus, the two principal justifications for quantifying belowground soil C are: 1) the recognition of the effects of C on the quality and fertility of the soil for precision agriculture; and 2) photosynthetic processes resulting in belowground C sequestration that is critically important to temporarily mitigate the consequences of anthropogenic CO₂ emissions into the atmosphere. However, belowground studies pose special challenges because underground structures, organisms, and processes are invisible to humans. Soil is a dynamic mix of living and dead plant matter, fungi, macro- and microfauna, plant exudates, and animal waste products, embedded in a matrix of solid, liquid, and gases. Thus, tinkering with this "black box" of soil *mélange* to study its components alters its function.

INTRODUCTION

The systematic study of belowground ecosystems requires new instrumentation that will allow *in situ*, non-destructive analysis of soil. The standard method entails extracting a soil core and subsequently analyzing it in the laboratory *ex situ*.^[1] Despite this traditional approach being labor-intensive, destructive, slow, and, consequently, very limited in its utility and scope, it is the accepted standard for soil analysis. Two newly emerging technologies, laser-induced breakdown spectroscopy (LIBS)^[2] and near- and mid-infrared spectroscopy,^[3] being field deployable offer significant advantages over the conventional method, although both are destructive and not *in situ* methods. A third novel method for soil elemental analysis is based on the spectroscopy of gamma rays induced by inelastic neutron scattering (INS) from the elements present in the soil.^[4–6] As the system based on the INS method is hovering about 30 cm above the ground (it is mounted on wheels), it is the only truly non-invasive *in situ* method that can be operated in a stationary mode or can be used for contiguous scanning of large fields. All of the newly emerging techniques are in their infancy and require further development and characterization; however, early reports suggest very attractive and unique features for each of the methods that cannot be embraced by a single device. A brief description of the INS system and its characteristics is given here.

BASIS OF THE INS SYSTEM

The INS method is one of the three alternatives of neutron activation analysis (NAA), a widely established tool for

elemental analysis. Of the three, the most widespread method is that of delayed NAA wherein a thermal neutron, a neutron in thermal equilibrium with the surroundings, approximately 0.025 eV, is absorbed by the nucleus of an element, thereby creating a radioisotope that decays to its ground state by a delayed emission of particles and/or gamma rays. Alternatively, by capturing a thermal neutron, an excited nucleus may decay instantaneously to its ground state by the emission of gamma rays: this process is referred to as prompt gamma ray analysis. In the third modality, a fast neutron is inelastically scattered by a nucleus leaving it in an excited state, which decays promptly to the ground state by emitting gamma rays. For this INS process to occur, the incident fast neutrons must be with energies that are above the threshold energies of approximately 5 MeV, depending on the element. Naturally, the scattered neutrons differ in their energies from the incident ones. Furthermore, the process of fast neutrons that lose energy via elastic scatterings may take up to few hundred microseconds depending on the scattering medium. Therefore, the first two processes are delayed after the INS process. Fig. 1 depicts these three processes schematically where one of them is marked as the INS that is used for carbon (C) detection. It is important to point out that during delayed neutron activation the irradiation with neutrons and the analysis of the sample occur at two different places, while in the two prompt processes, both irradiation and analysis take place, simultaneously resulting in high count rates and elevated background owing to data acquisition in the vicinity of the radiation source.

A typical INS system consists of a source of fast, 14-MeV, neutrons provided by a pulsed neutron generator (PNG).^[7] Gating the data acquisition system during the

Fig. 1 Absorption processes with thermal and fast neutrons. Asterisk (*) denotes a nuclear excited state.

neutron pulse reduces the background resulting from gamma rays because of thermal neutron capture with the net effect of improving the signal-to-noise ratio. The additional components include a gamma ray detection system, nuclear spectroscopy with data acquisition system, and a mobile cart with a power generator. The operating conditions are such that 14-MeV neutrons produced by the PNG are directed toward the soil's surface, where they penetrate and undergo inelastic scatterings with C and other elements; they also undergo elastic scatterings losing energy until they thermalize and get absorbed. During the INS processes, characteristic gamma radiation at 4.44 MeV is emitted from the C nucleus and is detected by an array of NaI detectors. The detected signal is processed and acquired in a form of a gamma ray spectrum in which all the gamma rays are recorded and their peak intensities analyzed. The peak intensities are proportional to the concentrations of the elements present in the soil. The counting time is typically set for 30 minutes, although the duration will depend on the required precision and minimum detection limits. Our instrument was initially calibrated, and measurements were taken by placing the entire system on the sand. However, in Fig. 2, the latest prototype of a mobile system set at an optimized height above the ground for detecting C is shown.

RESULTS

The initial system was calibrated with homogeneous mixtures of soil and 0, 2.5, 5, and 10 wt.% C. A sandpit 132 cm wide, 152 cm long, and 46 cm deep was filled, in turn,

Fig. 3 Calibration line of C yield vs. C concentration.

with each of the mixtures, and gamma ray spectra were acquired for 30 minutes. However, after measurement of the sand bulk density, the abscissa in the calibration line in Fig. 3 was expressed in units of C concentration gC/cc instead of % gC/g. The rationale for this conversion was that, in principle, the instrument detects C from a constant volume as delineated by the neutron flux and the solid angle subtended by the detection system.

Two gamma ray spectra were acquired for 30 minutes: one was in coincidence with the neutron pulse and corresponded to the INS events, Fig. 4A, and the second was acquired in between the neutron pulses, thus corresponding to prompt gammas following thermal neutron capture, Fig. 4B.

Field measurements in a pine stand, in an oak forest, and in a sandy patch were conducted with the initial system lying on the top of the soil. Using the calibration line shown in Fig. 2, these measurements were compared with the results of C analysis of five cores sampled from each site. The core samples were 5 cm in diameter and divided into five sections 5, 5, 10, 10, and 10 cm long. As the C distribution in soil is seldom uniform with depth, and the process of proper averaging C concentration in soil is complicated as a first order of approximation, the INS results were

Fig. 2 A mobile system for C detection deployed for field measurements.

Fig. 4 Typical “inelastic” (A) and “prompt” (B) gamma spectra measured in a pine stand.

Table 1 Comparison of C analysis by INS from the test volume vs. chemical analysis from the top 5 cm.

Site	INS (gC/cc)	Chemical analysis (gC/cc)
Pine stand (w, l)	0.099 ∓ 0.005	—
Pine stand (w/on, l)	0.079 ∓ 0.005	0.073 ∓ 0.021
Oak forest (w/o, l)	0.072 ∓ 0.004	0.085 ∓ 0.017
Sandy patch	0.026 ∓ 0.003	0.025 ∓ 0.002
Sandy soil	0.091 ∓ 0.007	0.104 ∓ 0.019
Sandpit (Cal.)	0.00	0.0004 ∓ —

compared only with the chemical analysis of the top 5-cm layer of the soil samples, i.e., the mean value of the top 5-cm layer from the five cores in each site. The results are summarized in [Table 1](#).

CONCLUSION

These limited results demonstrate the viability of the INS method for measuring C in soil *in situ*. Its unique attributes make it a one-of-a-kind system that is completely non-destructive. Furthermore, as the processes involved in

acquiring the measurements are very fast (picoseconds), the system can be operated in a stationary mode or used for scanning large areas using a system as shown in Fig. 2. The operating depth of the INS system is about 20–30 cm, which may depend on soil conditions. Clearly, with these unknowns, the system needs to be recalibrated with a much more realistic C depth distribution in soil. An additional unique attribute of the INS system is that the sample size in a stationary mode is large, over 30 L. Thus, small-scale lateral variations in the C distribution are averaged, so that fewer samples are required to represent a given area. Consequently, a more realistic calibration procedure using large volume excavations should be used in various soil types instead of core samples. Because the system provides multi-elemental analysis, in principle, it should be possible to partition the measured total C to organic and inorganic components by measuring calcium and magnesium and using stoichiometry to determine the inorganic C component. Other elements of interest that can be measured are nitrogen, potassium, and possibly phosphorus. Water content appears to have small effect on the measurements, because the hydrogen elastic scattering probability at these energies is small.

In summary, a novel multi-elemental analysis system for *in situ* non-destructive analysis of large volumes or large areas of soil was described. Further developments of the INS system will satisfy all the requirements posed for detecting C levels in soil.

Los Alamos, New Mexico, U.S.A.*

Abstract

Advanced methods of soil carbon (C) analysis are required to provide measurements of soil C at levels of accuracy and precision relevant to C trading and climate change research. Laser-induced breakdown spectroscopy uses a laser to interrogate a small soil sample from within intact soil cores. This method of analysis takes only a few seconds to accomplish, is cost-effective compared with conventional analysis methods, and can provide data on soil C distribution at 1 mm resolution in soil cores. This method correlates well with conventional analysis methods of the same soils and shows considerable promise as a cost-effective means to measure, monitor, and verify C sequestration in soils.

INTRODUCTION

The methods of carbon (C) analysis provide a set of analytical tools required to estimate changes in soil organic carbon (SOC) stocks with some precision.^[1] However, advanced analytical methods offer improved detection limits, increased ease of operation, and the potential to analyze samples in the field.^[2–6] These advanced methods could improve SOC measurements significantly and reduce uncertainties in C inventories. Improved accuracy and precision of C measurements are needed to support national and international policies on C emissions and C trading, but these improved methods must be more cost-effective than the existing methods. When fully developed and tested, advanced methods must optimize the amount of information about SOC pools per dollar spent and deliver C assessment data at less than 10% of the total cost of sequestration practices.^[7]

In this entry, we report preliminary calibrations of a new spectroscopic method for measuring total soil C that is based on atomic emission spectroscopy using laser-induced breakdown spectroscopy (LIBS).^[3,6,8–10] In this method, a laser is focused on a solid sample and forms a microplasma that emits light characteristic of the elemental composition of the sample. The emitted light is collected, spectrally resolved, and detected to monitor concentrations of elements via their unique spectral signatures. When calibrated, this method provides quantitative measurements of soil C in a sample. This method is readily adaptable to field-portable instrumentation, which would provide investigators a means to measure soil C in near real time and in remote locations^[11] or in a laboratory setting with high-throughput analysis. We evaluated LIBS

for its potential to measure total soil C at 1-mm intervals along a soil profile. C distribution data at this resolution can provide whole-profile C inventory estimates as well as new estimates of measurement uncertainty.

HIGH-RESOLUTION LIBS METHODOLOGY

Strong carbon C(I) emission lines at 247.8 nm are selected for the evaluation of LIBS.^[3,6,12,13] An Nd:YAG laser (Spectra-Physics Lasers, Mountain View, California, U.S.A.) at a wavelength of 1064 nm (50-mJ pulses of 10 ns) is focused with a lens of 50-mm focal length on each soil sample (Fig. 1). The emitted light is collected through a fused silica fiber optic cable pointed at the plasma from a distance of about 50-mm. A spectrograph of 0.5 m focal length resolves the light that is then detected using a gated intensified photodiode array detector. Intact soil cores are placed in the instrument for analysis. A stepping motor and movable stage are coupled to transport the cores through the LIBS instrument and allow collection of spectra each 1 mm along the length of the core. Peak areas are integrated to estimate signal intensities for each spectrum. The background signal was obtained from a shot into a blank sample and was subtracted from the spectrum. The C signal was ratioed to the signal of Si at 251 nm to minimize shot-to-shot instrumental variation. Typical measurement volumes for the LIBS analysis are 1–5 mm³.

C concentrations from each 1 mm along the core are obtained by collecting 20 shots from different points within the 1-mm band. The stepping motor moves the core slightly after each shot to prevent multiple analyses of a single

Fig. 1 Schematic representation of LIBS instrument, showing microplasma collection, detection, and spectral resolution of a sample.

location. C peak areas from the 20 shots are averaged into the point estimate of C concentration at each 1-mm location. Finally, an average C concentration for each 2.5-cm interval is computed using the estimates from all 1 mm measurements and by averaging these over the 2.5-cm interval. The averaging over the 2.5-cm interval allows comparison of LIBS data with dry combustion data from the same 2.5-cm intervals taken from core samples after LIBS analysis.

Intact soil cores are extracted using a hand-operated coring apparatus. Any method to remove an intact core should be adequate, including a Giddings probe or core from shallow drill rig operations. The core is collected in a plastic tube. After description of the horizons, a slit of approximately 10 mm is cut in the plastic tube to allow laser access. The core is then cycled through the LIBS instrument, and data are collected each 1 mm along the core. Twenty shots are averaged per step.

C peak areas are estimated from the raw data and plotted with core depth. The LIBS data are then summed over a 2.5 cm core depth, and the geometric mean of the LIBS measurements is computed for each interval. The geometric mean is used to minimize the effects of large variance in the LIBS-measured C concentration due to heterogeneity in the C distribution in each core (Fig. 2). After LIBS analysis, the core is sectioned into 2.5-cm intervals and prepared for dry combustion analysis. Comparison between the LIBS data and the dry combustion data is reasonably consistent, as shown in the regression of LIBS data against the dry combustion data (Figs. 3 and 4).

RESULTS

An example of raw LIBS data with depth is shown in Fig. 2. These data indicate the variation of the C signal with depth, a feature that is not collected with conventional methods. This variation can be used to estimate the C concentration in the core as well as the uncertainty of the concentration estimate. In the raw form, the data are not comparable with conventional analysis data. Therefore, we integrated the

Fig. 2 Raw data from LIBS data at 1 mm step size in an intact soil core. Since Si is ubiquitous in soils and present at much greater total concentrations, small variations in Si concentration did not appreciably affect the C/Si ratio. Thus, differences in C/Si values are interpreted as changes in C concentration.

Fig. 3 Integrated LIBS data and dry combustion data from the same core. LIBS values were estimates computed using the measurement made at each 1 mm along the core.

LIBS data into 2.5-cm intervals to compute average C concentrations within a given interval. Dry combustion analyses obtained from the same 2.5-cm intervals gave the data by which we could compare the two methods.

The data in Fig. 3 show a reasonable agreement between the geometric mean of the LIBS data from each 2.5-cm interval and the dry combustion data (Fig. 3). The correlation found regressing the two data sets was good for the core used in this example ($R^2 = 0.982$; Fig. 4) and ranged from 0.7 to 0.98 for 12 other cores (data not shown).

SUMMARY

These initial data show promising application of the high-resolution method for the analysis of intact soil cores with LIBS. The LIBS data are generally comparable to the data from conventional methods, but acquisition of the LIBS data is considerably more rapid and at higher resolution. Extraction and collection of the spectra from each of the cores take about 30 minutes with the LIBS instrument, whereas an additional time period of 7–10 days is required to complete the analysis via dry combustion. The cost

savings, in terms of man-hours, of the LIBS analysis compared favorably to dry combustion. Sample extraction and preparation require only minutes using LIBS, and analytical results are usable within an hour of sampling, whereas days to weeks of laboratory preparation and handling are required for dry combustion analysis.

High-resolution analysis of intact cores can also provide routine estimates of measurement uncertainty, whereas uncertainty estimates from dry combustion are difficult because of the need for multiple subsamples. The variability of C concentrations from one sample step to the next is clear (Fig. 2). Part of this variation is due to the heterogeneity of the formation of soil C in the soil, and part is due to C from included material (e.g., roots) or dilution of C with material that does not contain C (e.g., quartz grains). The amount of data collected from a core using LIBS is basically a C measurement each 1 mm; when composited into 2.5-cm intervals, the LIBS data yield an uncertainty estimate based on a high density of measurements. Dry combustion, on the other hand, requires dozens of measurements from the same interval of the core to approximate the estimate from the LIBS data.

The LIBS analyses are usually conducted on samples directly extracted from the soil with no additional preparation. The advantages of this method are in its speed and its apparent accuracy and precision. One disadvantage of the method is the cost of building a LIBS instrument or adapting a commercial instrument to this application. Efforts are underway to commercialize the LIBS instrument for high-resolution C analysis, and such a product was expected by 2007. A second disadvantage is the inclusion of all components of the soil core in the analysis. Thus, roots, rock fragments, and other material in the soil are part of the C analysis for the entire core. This feature explains some of the variability in the C signal as mentioned earlier.

The high-resolution method requires large-scale, systematic evaluation before it is accepted and used as a method for C analysis of soils. The promise shown in these results, however, suggests that such a study needs to be undertaken at an earliest opportunity.

Carbon: Physical Protection

Abstract

The protection of soil organic carbon (SOC) from mineralization by physical factors arises because of the multiple interactions of SOC with the other components of the soil matrix and the physical environment. It has been investigated by considering the properties of SOC in different physical fractions (including macroaggregates, microaggregates, and organic-mineral complexes) of soils, by attempts to visualize the distribution of SOC in soils and relating this to the factors controlling the presence and activity of decomposer organisms, and as components in simulation models. The main mechanisms whereby SOC is physically protected are: 1) encapsulation within aggregates where it is isolated from decomposer organisms; 2) stabilization by sorption of SOC at reactive colloid (e.g., clay or amorphous iron or aluminum) surfaces; and 3) where the environmental conditions, such as oxygen availability, restrict decomposition, or because of the extremes of physical conditions in the soils as a whole, such as extremes of temperature or very high water/very low oxygen content. Physical protection is not, however, a permanent state because the protection mechanisms tend to retard rather than completely halt decomposition, and because aggregate formation and disruption is a dynamic process, sorption can be followed by desorption, and environmental conditions change. Nonetheless, the emerging view is that accessibility of SOC to decomposer organisms is the dominant factor governing recalcitrance of SOC rather than inherent resistance to decay.

INTRODUCTION

Soil organic carbon (SOC) is the dead and decaying remains of plant, animal, and microbial organisms and their wastes. Heterotrophic soil organisms can utilize SOC directly as a source of organic carbon for biosynthesis and oxidize it to release energy, a process variously referred to as carbon mineralization, heterotrophic respiration, or just soil respiration. Carbon mineralization gives rise to a variety of intermediate products with different mean residence times in the soil, and, under aerobic conditions, ultimately carbon dioxide (CO₂) which diffuses into the atmosphere. In the context of this entry, physical protection refers to any set of conditions which limits the rate at which heterotrophic organisms can utilize SOC and the potential loss of carbon as CO₂ from the soil carbon pool. The tendency for soil to protect physically SOC from mineralization is affected by the interactions between the SOC and the soil mineral fraction and the spatial arrangements of the soil mineral (inorganic) components around the SOC (Fig. 1). Soils with large clay contents, and therefore a substantial surface area on which molecules can be absorbed, tend to have a larger SOC content than those with a lower clay content, and soils in which stable aggregates form (which may be related to clay content also) will tend to hold a greater SOC content relative to soils with less stable

structure. In both cases, the physical protection, i.e., the protection from biological attack leading to carbon mineralization, is related to the spatial arrangement and interactions of the SOC and the soil mineral components.^[1] Land use by humans affects the rates of carbon mineralization in soils, usually causing acceleration of SOC decomposition, due to disruption of the mechanisms of physical protection. Unprotected SOC that is dissolved or suspended in water may also be lost from the soil by leaching or in surface runoff from top soils and this too may result from physical protection being removed as a result of the action of water in either dispersing soil aggregates or components of the SOC dissolving in it.

PHYSICALLY DEFINED FRACTIONS OF SOC AND RELATIONSHIP TO PHYSICAL PROTECTION

The practice of considering SOC on the basis of physically defined fractions is well established. In these approaches, soils are usually dispersed to stable microaggregates and separated into fractions on the basis of size or density.^[2,3] In reality, it is rarely the “clean” organic matter fractions that are separated into the different fractions, and the fractions usually contain varying amounts of inorganic soil material. Nonetheless, physical fractionation provides a useful way

Fig. 1 Spatial arrangement of soil organic and inorganic components and soil microorganisms and water in soil macroaggregates and microaggregates and, at the smallest scale, SOC sorbed on clay (colloid) surfaces.

to understand SOC decomposition processes and to detect the effects of different soil management on SOC. Separation using procedures that discriminate on the basis of size, solubility, or density, and sometimes several in combination, follows the rationale that the fragment size of SOC decreases with time and the density of the fraction in which SOC is recovered increases with time because of increasing association with relatively inorganic soil components. The predominantly insoluble, particulate components of fresh plant litter are represented by particulate organic matter (POM) in some schemes and in the sand-sized [i.e., 50 μm (or 63 μm) to 2000 μm equivalent spherical diameter] fraction in other schemes. It is essential to realize that the SOC recovered in the sand-sized fraction does not necessarily have an association with actual sand. POM is often characterized by having relatively low density (close to 1 g cm^{-3}) and it is therefore frequently recovered as a low density fraction, or the so-called light fraction (LF). Although defined by different operational procedures, POM, sand-sized SOC, and LF SOC share several similar characteristics—they are usually relatively large-sized materials, relatively labile, and have little, if any, intimately associated inorganic material. SOC is subject to comminution (often by the feeding processes of soil organisms) and fragmentation as a result of physical disintegration, biological degradation, and assimilation into microbial biomass and extracellular exudates, so that the overall fragment size declines with time. Thus, older SOC is recovered in progressively smaller (silt- and then clay-sized) fractions. Unless very harsh dispersion procedures are used, these fractions are likely to be aggregations of sand and/or silt particles with SOC rather than isolated silt or clay particles. As a result of residence in the soil and exposure over time to reactive inorganic surfaces, SOC develops progressively more intimate associations with inorganic

materials, particularly clay particles and amorphous colloids. As the inorganic components tend to have greater density than SOC, older SOC tends to be recovered in fractions with greater density and smaller size. Simultaneous with the passage of carbon in plant litter from large-sized and low density fractions to smaller-sized and higher density fractions, aggregations of soil particles are formed and breaking down continuously. This occurs because of the influence, for example, of feeding by soil fauna (e.g., earthworms, collembola, or mites), freezing and thawing, wetting, and drying and management, such as tillage, and is superimposed on the size and density journey of SOC. Thus, fresh plant residues or recent exudates which may be valuable microbial substrates can become encapsulated in soil aggregates where they may be isolated from microorganisms or located in locations where the environmental conditions retard decomposition.^[4] This can lead to old but potentially labile SOC being recovered in relatively dense fractions; Dungait et al.^[5] reviewed the recalcitrance of plant and microbial derived SOC and concluded that accessibility of SOC to decomposer organisms was the dominant factor governing recalcitrance of SOC rather than the inherent properties of the SOC at the molecular level.

MECHANISMS OF PHYSICAL PROTECTION

Physical protection of SOC occurs because either the biological decomposition agents (soil organisms or their extracellular enzymes) are spatially isolated from the SOC or because local physical conditions prevent them from using the SOC in their vicinity.

Spatial Isolation

Spatial separation of SOC from heterotrophic organisms operates at different scales, which correspond to the size and motility of the organisms and the ability of the organisms to disrupt the mechanisms of protection and access the SOC.

At the molecular scale, the interactions between SOC and soil mineral colloids are complex. The behavior of both SOC and soil inorganic colloids (clay minerals and amorphous iron and aluminum colloids) is dominated by the physical and chemical properties distributed over their relatively vast surface areas. Most mineral and organic colloids in soil carry a net negative surface charge and thus, at close proximity, are repelled from each other. Opposing this repulsion, van der Waal's forces of attraction operate over slightly longer ranges. Therefore, the proximity of SOC to a mineral colloid surface is determined by the balance between the two opposing forces. Bacteria also behave as organic colloids and this influences their ability to access SOC at this most intimate scale. At the nanoscale, the interlamellar spaces of certain clays have hygroscopic properties which draw in and trap dissolved SOC. The SOC

is physically protected from decomposition if the dimensions of these spaces are too small for soil microorganisms or extracellular enzymes to access the SOC. At the micro- and submillimeter scale, adsorption of SOC onto mineral surfaces of clay and silt particles because of a range of properties including adhesion, cation bridging, and hydrogen bonding leads to persistent complexes between SOC and mineral surfaces.

Clay and silt particles, upon which SOC is sorbed, may further combine to form microaggregates, encapsulating or occluding SOC and thereby increasing its physical protection. Microaggregates are comprised of inorganic and organic components bound together under the influence, at least in part, of biological phenomena including, on the one hand, the adhesive properties of the SOC, microbial extracellular polymeric substances and rhizoxudates, and mucilage from soil invertebrates, and on the other, the enmeshing action of fungi and fine roots. The SOC encapsulated in microaggregates is rendered relatively stable because of the spatial isolation from external soil microorganisms and internal physical conditions that limit microbial activity within aggregates. However, soil microaggregates are transient because the biological phenomena that contribute to stability are dependent on the persistence of the metabolic activity of organisms whose contributions subside as their substrate (i.e., SOC) is exhausted. Larger-scale aggregation, in a continuum of size ranging from microaggregates to peds, is progressively controlled by physical processes that impose an upper size limit, i.e., water infiltration, erosion, compaction, and tillage. The size of soil aggregates is usually inversely proportional to the amount of energy needed to disrupt them; thus, microaggregates afford the most protection to encapsulated SOC.

The activity of earthworms is of particular importance due to the huge mass of casts produced, e.g., 20 to 30 kg m⁻² yr⁻¹ in temperate pastures. Cast production initially enhances carbon mineralization and nutrient release because of the stimulation of the microorganisms ingested with the organic residues by the introduction of moisture and mucus and physical fragmentation by grinding with ingested mineral particles during passage through the gut. These effects are, however, transient with progressive stabilization of organic carbon in aging casts as labile organic components are mineralized or become physically unavailable through interactions with coingested mineral particles, thereby providing a route for the stabilization of SOC.

Physical Constraints on SOC Decomposition

Even under circumstances where both SOC and heterotrophic soil organisms are simultaneously colocated, physical conditions including temperature, water availability, and oxygen availability may restrict carbon mineralization, because biological processes can only operate within a range of environmental tolerances. Where conditions in the soil exceed these thresholds, heterotrophic activity may be

repressed, but if inputs from photosynthesis can proceed, SOC may accumulate (see below).

Biological processes, including carbon mineralization in soils, respond to changes in temperature. Assuming that there is no water limitation, the optimum temperature range for metabolic activity is around typically 25–30°C. The magnitude of change to the rate of SOC decomposition as temperature increases by 10 K is described by the Q10 parameter and usually has a value of around 2, except at the limits of biological activity. The upper limit for biological activity in soils is around 50°C, because most proteins that control metabolic function (including the enzymes that catalyze SOC decomposition) denature above this limit and Q10 falls rapidly as the upper temperature limit is approached. At low temperatures, biological activity increases rapidly as the temperature increases away from 0°C. Although some biological processes can be detected even at subzero temperatures, their contribution to net carbon mineralization is negligible. Moreover, under natural circumstances, it is difficult to separate the effect of extreme temperatures from water availability in soils which is limiting at both high and low temperatures. Where photosynthesis proceeds but carbon mineralization is retarded by temperature, SOC may accumulate. Thus, the large stocks of SOC in the Cryosols of boreal and tundra regions at high latitudes are particularly vulnerable to warming, and in the boreal regions which contain large SOC stocks protected from carbon mineralization by low temperatures, the effect of warming will be particularly marked.

Under conditions of non-extreme temperature, the availability of water and oxygen is closely linked. In general, the amount of water in the soil is inversely related to the amount of oxygen in the soil. Most soil organisms are obligate aerobes, requiring oxygen to act as the terminal electron acceptor during respiration. When soils are waterlogged, the rate of diffusion of oxygen through water to biological organisms is too slow to allow aerobic respiration to proceed. However, facultative and obligate anaerobes become active under these conditions allowing reduced rates of carbon mineralization to proceed by fermentation, which ultimately leads to the production of gaseous methane, and other incompletely oxidized terminal products in solution, such as ethanol.

At the scale of the individual aggregate, water and oxygen are not uniformly distributed. Water tends to occupy the pores with the smallest neck diameters under non-saturated conditions in soils, drawn and held strongly in place by capillarity, restricting the movement of oxygen (Fig. 2). Consequently, locations at the interior of aggregates may be persistently anoxic, regardless of the moisture content of the wider soil environment. Anoxic conditions are likely to arise rapidly in newly formed aggregates where fresh organic carbon is newly encapsulated. These include the casts of earthworms which are important macroinvertebrate “soil engineers” in many soils.

Fig. 2 The DLVO^[6,7] model showing the decay with distance of electrostatic repulsion and van der Waal's forces of attraction and the net interaction energy. At very close proximity (typically at the submicrometer scale), the model predicts net attraction between surfaces that display colloidal properties (e.g., clay particles, SOC, microorganisms, and extracellular enzymes), while at slightly greater distances, there is net repulsion, before at greater distances the attractive van der Waal's forces completely overwhelm electrostatic repulsion. The distances over which electrostatic repulsion operates is influenced by electrolyte concentrations because positively charged counterions neutralize some of the negative surface charges. The two regions where net attractive forces apply can form a diffuse double layer at colloid surfaces. Here, microorganisms and SOC may be simultaneously present and may interact leading potentially to carbon mineralization, but toxic compounds may also be held in the same vicinity which may suppress carbon mineralization.

CONCLUSION

Physical protection of SOC is not a single process, but a set of processes operating at different scales that collectively lead to the rate of decomposition of SOC being restricted compared to that which would occur in their absence. The key components of physical protection are encapsulation of the SOC at sites where it is isolated from microorganisms or where the environmental conditions retard decomposition, or stabilization on colloid surfaces retarding microbial attack, or because of the overall restrictions on decomposition activity imposed by the wider environmental conditions such as temperature or oxygen availability. Many soil management practices, such as tillage activities and irrigation, disrupt the mechanisms of physical protection of SOC, which may be observed as the loss of aggregate structure in

poorly managed cultivated soils. The breakage of soil aggregates exposes the encapsulated SOC to the agents of carbon mineralization, and the removal of organic carbon and nutrients starves the organisms in the soil that promote aggregate formation. In the absence of structure, the soil may slake when wetted because the aggregates are less stable in water, producing a dense layer impermeable to water and air. Soil compaction by heavy machinery or livestock can crush soil aggregates and reduce the number of large pores for water and air infiltration, creating an anaerobic compaction layer in the soil in which the nutrient turnover that is driven by carbon mineralization is reduced. Thus, in addition to being of fundamental interest to advance the understanding of SOC dynamics, appreciation of the sensitivity of SOC to changes in physical protection mechanisms is important for soil management.

Houston, Texas, U.S.A.*

Abstract

Carbonate dissolution and precipitation are among the most important chemical reactions in soils. Carbonates precipitate as coatings on soil particles and in soil pores that may result in the cementation of particles. Other important reactions involving carbonate minerals are adsorption and/or precipitation of some anions and cations on their surfaces which have an impact on the mobility of essential plant growth elements (e.g., ferrous ion, ferric ion, zinc ion, hydrogen phosphate, and dihydrogen phosphate) and elements of environmental concern [e.g., cadmium ion and plumbous ion (Pb^{2+})]. Carbonates (e.g., calcite and dolomite) are also added to raise the pH of acid soils (i.e., carbonates as liming agents) or to immobilize heavy metals (e.g., Pb^{2+}) in contaminated soils through the precipitation of relatively insoluble carbonates (e.g., lead carbonate). These important processes have led to many studies of carbonate reactions and occurrences in soil environments.

INTRODUCTION

There are approximately 150 carbonate minerals that occur in nature; however, most of these carbonates are relatively rare. The most common rock-forming carbonates are calcite (CaCO_3) and dolomite ($\text{CaMg}(\text{CO}_3)_2$), which account for over 90% of natural carbonates.^[1] CaCO_3 , $\text{CaMg}(\text{CO}_3)_2$, siderite (FeCO_3), and ankerite ($\text{Ca}(\text{Mg,Fe})(\text{CO}_3)_2$) are the most common carbonates that occur in sedimentary environments.^[2] Carbonates are very common in soils, and they either form during soil formation (i.e., paedogenic) or are inherited from parent materials (i.e., detrital or lithogenic). The most common carbonates that occur in soils are CaCO_3 , magnesium (Mg)-calcite ($\text{Ca}_x\text{Mg}_{1-x}(\text{CO}_3)$), and $\text{CaMg}(\text{CO}_3)_2$. Aragonite (CaCO_3) occasionally occurs in soils, and FeCO_3 has been reported to occur in some soils.^[3]

STRUCTURE AND COMPOSITION

The carbonate ion (CO_3^{2-}) is the basic structural unit for all carbonate minerals. The large planar CO_3 group occurs as a rigid structure with the carbon (C) atom occupying the center, which is surrounded by three oxygen atoms arranged in an equilateral triangle. The linkage of the carbonate group to other cations has minimal effect on the ideal C–O bond angle of 120° in the CO_3 group.^[4] The non-hydrous carbonates can be grouped according to their structure into the calcite group, dolomite group, or the aragonite group (see Table 1). Hydrated carbonates have entirely different crystal structures, and most crystallize in the monoclinic crystal system (Table 1).

Calcite group minerals crystallize in the hexagonal crystal system. The structure of CaCO_3 , which is the most common calcite-group mineral, is a distorted sodium chloride type structure where calcium (Ca) alternates with CO_3 . This distorted structure places Ca atoms in a face-centered rhombohedral unit cell (Fig. 1), which is the morphologic or cleavage cell. The smaller true unit cell is an elongated rhombohedral unit cell, which is easily compared to the hexagonal unit cell (Fig. 1). Magnesite, FeCO_3 , rhodochrosite (MnCO_3), and smithsonite (ZnCO_3) are isostructural with CaCO_3 (Table 1).

Aragonite-group minerals crystallize in the orthorhombic crystal system. In this group, large divalent cations (e.g., ionic radii > 0.1 nm) do not permit a stable sixfold coordination and, therefore, result in a ninefold coordination configuration. Aragonite, which is a higher temperature and pressure CaCO_3 polymorph (CaCO_3 is the stable polymorph at room temperature), has CO_3 groups in two structural planes rather than the single structural plane of CaCO_3 . Witherite (BaCO_3), strontianite (SrCO_3), and cerussite (PbCO_3) are isostructural with aragonite (Table 1).

The third major group of carbonate minerals, the dolomite group, crystallizes in the hexagonal system. Their structure is similar to calcite-group minerals, except that different cations (e.g., Ca–Mg, Ca–Fe, and Ca–Mn) alternate along the c-axis. Because of this arrangement of alternating cations, the symmetry of dolomite-group minerals is reduced compared to the calcite-group minerals. $\text{CaMg}(\text{CO}_3)_2$ has Ca and Mg alternating along the c-axis. $\text{Ca}(\text{Mg,Fe})(\text{CO}_3)_2$ and kutnahorite ($\text{CaMn}(\text{CO}_3)_2$) are isostructural with $\text{CaMg}(\text{CO}_3)_2$ (Table 1).

Various cations may substitute into the carbonate structure. For example, Mg^{2+} may substitute for Ca^{2+} in the

Table 1 Representative unit cell formulae and selected properties of common carbonates.

Carbonate group	Ideal unit cell formula	Crystal system	Specific gravity
<i>Calcite group</i>			
Calcite	CaCO ₃	Hexagonal (rhombohedral)	2.71
Magnesite	MgCO ₃	Hexagonal	3.00

CaCO₃ structure. These Mg-substituted calcites are called magnesian calcites or Mg-calcites. Mg-calcites containing up to 20 mol% MgCO₃ are found in skeletal materials of marine organisms, and even higher concentrations of Mg (e.g., 45 mol% MgCO₃) in the CaCO₃ structure have been synthesized at high pressure and temperature. Most soil Mg-calcites, however, contain

Fig. 1 Structure of CaCO₃. Unit cell parameters for a and c are shown for the hexagonal unit cell. The elongated rhombohedral, true unit cell contains two CaCO₃; the two CO₃ groups are shown ($\alpha_R = \alpha_{\text{rhombohedral-cell}}$). The morphological or cleavage cell contains four CaCO₃ (face-centered rhombohedral cell). Note that ionic radii for Ca, C, and O are not drawn to scale.

less than 10 mol% MgCO₃.^[3] Due to the smaller ionic radius of Mg²⁺ as compared to Ca²⁺, the a and c unit cell axes decrease in length, as the substitution of Mg²⁺ increases in the structure of CaCO₃.^[7] Detailed discussion on the substitution of cations into carbonate structures can be found in the studies by Chang et al.^[5] and Reeder.^[8]

OCCURRENCE IN SOILS

Carbonates are common in many soils of the world, particularly in soils of subhumid to arid regions. CaCO₃ is the most common carbonate in soils, but CaMg(CO₃)₂, aragonite, and FeCO₃ are also found in certain soils. Carbonates may be either inherited into soil or form directly via precipitation processes. The most common sources and mechanisms for carbonate occurrences in soils are as follows: 1) inheritance from parent material; 2) precipitation following dissolution of soluble Ca-bearing minerals; 3) precipitation by reaction of CO₂-charged water with Ca²⁺ released by decomposition of plant residues; 4) deposition of windblown carbonates at the soil surface and subsequent translocation within the soil by solution and precipitation; 5) precipitation by interaction of Ca²⁺ in

rainwater entering the soil and combining with HCO_3^- from CO_2 -charged water; 6) precipitation from CO_2 -charged natural surface or irrigation water containing Ca^{2+} ; and 7) precipitation in soils from groundwater that has moved through carbonate-containing soils or sediments.^[3]

CaCO_3 and Mg-calcite are the two carbonates that commonly precipitate in soils. Although all of the carbonates commonly found in soils may be inherited, aragonite and $\text{CaMg}(\text{CO}_3)_2$ are almost always inherited. Paedogenic $\text{CaMg}(\text{CO}_3)_2$ has been reported to occur in some saline, alkaline soils, but generally, its formation in soil is very rare.^[9] Mg-calcite with high MgCO_3 mole% (e.g., > 10 mol%) is typically inherited in soils from marine sediments (i.e., from biogenic Mg-calcite). FeCO_3 is relatively unstable in soil environments and is not known to form directly in soils. Mg carbonates are very rare in soils, but hydrated Mg carbonates (e.g., hydromagnesite and nesquehonite) may form at the surface during the evaporation of solutions high in Mg^{2+} and HCO_3^- .^[10] Mechanisms by which carbonates precipitate in soils are provided in the following section.

The distribution of carbonates in a soil profile depends on the climate, soil chemical properties, and degree of leaching through the profile. In many arid soils, carbonates are common secondary products in the top horizons (e.g., A and B horizons). As a general rule, carbonates tend to be leached or removed from the upper horizons with increasing leaching or rainfall. Carbonates leached from upper horizons may precipitate as secondary carbonates in the lower horizons where they may form carbonate-cemented layers (e.g., petrocalcic horizons).

Sodium carbonates may occur at the soil's surface in arid regions where soil salinity is high. Highly soluble sodium carbonates precipitate at the surface during the periods of evaporation, and such conditions produce soil pH values of higher than 8.5.

FORMATION

Carbonate dissolution or precipitation is dependent on several factors, such as the partial pressure of dissolved CO_2 in solution and temperature. A typical reaction for the dissolution of CaCO_3 may be expressed as a function of CO_2 as follows

The equilibrium constant (K^0) for this reaction at 25°C is as follows

$$K^0 = \frac{(\text{Ca}^{2+})(\text{HCO}_3^-)^2}{P_{\text{CO}_2}} = 10^{-5.90} \quad (2)$$

where P_{CO_2} is the partial pressure of CO_2 and brackets denote activities.^[11] The reaction may also be expressed as a function of H^+ as follows

with the respective equilibrium constant at 25°C being

$$K^0 = \frac{(\text{Ca}^{2+})(\text{HCO}_3^-)}{(\text{H}^+)} = 10^{+1.92} \quad (4)$$

Eqs. 2 and 4 indicate that the dissolution of CaCO_3 (and other carbonates) is favored with increasing CO_2 pressure and decreasing pH. Conversely, the degassing or removal of CO_2 from solution or an increase in pH will favor CaCO_3 participation. The equilibrium pH of a solution in contact with CaCO_3 at atmospheric CO_2 pressure ($10^{-3.5}$ bar P_{CO_2}) is 8.3. Detailed discussion on carbonate solution chemistry can be found in the studies by Lindsay^[11] and Langmuir.^[12]

PROPERTIES

Calcium carbonate has an influence on several soil properties, e.g., soil pH, adsorption-desorption, and soil cementation. Most soils that contain calcium carbonate will have a pH in the range of 7.1–8.5, in which the carbonate acts as a pH buffer. The surfaces of CaCO_3 are reactive, and various ions may adsorb or interact at the crystal's surface. For example, Mg^{2+} , zinc ion (Zn^{2+}), Cu^{2+} , ferrous ion (Fe^{2+}), and Al^{3+} may replace Ca^{2+} on exposed surface lattice sites. The reactive surfaces of carbonates may adsorb essential plant ions such as hydrogen phosphate, dihydrogen phosphate, Fe^{2+} , ferric ion, Zn^{2+} , and Mn^{2+} and adversely affect their availability for plant uptake. Iron deficiency chlorosis in plants has been attributed to the interaction of Fe and HCO_3^- in calcareous soils.^[13,14] Other factors, such as quantity, mineralogy, and crystallinity of iron oxide phases in the soil, may also contribute to plant Fe chlorosis in calcareous soils.^[15]

The precipitation of carbonates on soil particles and in soil pores may form layers (i.e., calcic horizons) that impede the movement of water.^[16] Some layers may become indurated or cemented (i.e., petrocalcic horizons) and force water to move laterally in the soil.

Soil carbonates play an important role in the global C cycle although their role in the greenhouse effect is not well understood.^[17] Soil inorganic C (i.e., lithogenic and paedogenic carbonates) accounts for about one-third of the total C in soils; the remaining two-thirds of soil C is comprised of organic C. Soil organic C is the primary C pool in humid regions, whereas carbonates are the predominant C pool in arid and semiarid regions. The role of paedogenic carbonates in atmospheric C sequestration is not clear; however, the flux of paedogenic carbonates with the atmosphere has been estimated as $0.023 \text{ Pg C yr}^{-1}$, with a turnover time in the range of 30,000–90,000 years.^[18]

Carbonates such as CaCO_3 have been suggested for use in the remediation of plumbous (Pb)-contaminated soils where plumbous ion reacts with HCO_3^- to form insoluble Pb carbonates. Other soil contaminants (e.g., barium ion

and cadmium ion) may also be immobilized through carbonate precipitation with the addition of more soluble carbonate amendments.^[19]

In summary, carbonates are of great importance in soils because they have considerable influence on the physical and chemical properties of soils, they have an important role in the global C cycle, and, occasionally, carbonates are the predominant mineral phases that occur in soils of arid and semiarid regions.

Abstract

Secondary or pedogenic carbonates (PCs) are those that are formed through the processes responsible for the soil development. The PC is an important part of the global carbon cycle. Global estimates are far from complete. The stable isotope technique is used to calculate the amount and rate of secondary carbonates.

INTRODUCTION

Secondary or pedogenic carbonates (PCs) are those that are formed through the processes responsible for the soil development. They are found in relatively dry soils and developed under natural good drainage and vegetation comprising grass and shrubs mixture.^[1] Total soil inorganic carbonate (SIC) has been estimated globally to be about 800 Pg in Aridisols and Entisols of arid regions, mainly in the caliche layers.^[2] Other estimates of total SIC in world soils include 720 Pg C,^[3] 695–748 Pg,^[4] and 750–947 Pg.^[5] The differences among estimates are a result, at least in part, of the difficulty of differentiating between primary carbonates (lithogenic carbonates) and carbonates of secondary origin or PCs.^[6] Reliable estimates on PC are to be calculated.

In soils, secondary carbonate species are calcite and magnesian calcites ($\text{Ca}_x\text{Mg}_{1-x}$).^[7] They occur as filaments, nodules, seams, or diffuse impregnations in non-gravelly materials; in gravelly materials, carbonates occur as pebble coatings, bridges, diffuse interstice fillings, and pendants secondary carbonates on the lower surface of pebbles, and cobbles form carbonate pendants with a complex, layered structure.^[8] Secondary carbonates, as a more stable pool than organic carbon (C), can sequester substantial amounts of C and are important constituents of many soils.

SECONDARY CARBONATE FORMATION

The partial pressure of carbon dioxide (CO_2) gas and pH of the soil solution play major roles in the precipitation of carbonates. The partial pressure of CO_2 in the atmosphere is about 3×10^{-5} MPa ($\sim 3 \times 10^{-3}$ atm). In the soil, because of

microbial activity and oxidation of organic matter, the partial pressure of CO_2 is much higher than in the atmosphere and it varies with time.

The reactivities between CO_2 and water are shown in Eqs. 1–5 as follows:

Secondary carbonate accumulations are commonly found in the pH range of 7.3–8.5. To form calcite in soils, a sufficient amount of calcium must be present in the soil solution.

Calcite forms through the following reaction:^[9]

As shown in Fig. 1,^[10] the ratio of $\text{H}_2\text{CO}_3/\text{HCO}_3^-$ is unity at about pH 6.4. This ratio increases tenfold for each unit decrease in pH. Below pH 6, almost all the dissolved carbonate species are in the form of H_2CO_3 . Equimolar of CO_3^{2-} and HCO_3^- occurs at pH 10.3, and between pH 6.4 and 10.3, the dominant carbonate ion species is HCO_3^- .^[11]

Calcite accumulation may develop relatively rapidly in gravelly soils. The process is rather slow in non-gravelly, sandy, or loamy soils. Continuous accumulation results in the formation of a calcic and/or petrocalcic horizons.

MORPHOLOGY OF SECONDARY CARBONATES

The morphology of secondary carbonate crystals is controlled mainly by the rate of crystallization and by Mg^{2+} and Na^+ contents of the precipitating waters.^[12] Most of the visible individual PC crystals in soils^[13] have diameters of 0.3–1.0 μm . In the soil matrix, soil particles inhibit the crystal growth, but in pores, the crystals tend to be larger in size. Fine crystal size is also attributed to the relatively high solubility of soil carbonates or the flush of high concentration of Ca^{2+} introduced to the soil system.

The surface morphologies of carbonate pendants and lithogenic carbonate pebbles have different features (Fig. 2). PCs occur in the form of microscopic calcite crystals, which are strongly clustered, with individual crystal sizes ranging from about 0.1 mm to crystal clusters of 3 mm diameter. Depending on soil matrix composition, microsparite, sparite, and micritic fabrics can form.^[14]

CALCULATION OF PC IN SOIL USING STABLE ISOTOPES

The C isotope geochemistry technique is used to distinguish between pedogenic and inherited carbonate.^[15]

Carbon isotope ratios are given as relative deviation in per mil from the isotope ratio in the Pee Dee Belemnite (PDB; specimen of *Belemnitell americana* found in the Pee Dee formation of South Carolina) standard.^[16] Because PDB has been exhausted, most of the researchers report $\delta^{13}C$ values relative to Vienna PDB as follows:

$$\delta^0/_{oo} = [(R_s - R_{std})/R_{std}] \times 1000 \quad (7)$$

where R_s is the isotope ratio for an element in a compound and R_{std} is the corresponding isotope ratio in a standard.

The difference between $\delta^{13}C$ values of parent material carbonate and PC can be used as an indicator of dissolution–precipitation process taking place in soil horizons. The amount of newly formed carbonates can be calculated from the C isotopic composition:^[16]

$$\% \text{Pedogenic carbonate} = \frac{\delta^{13}C(\text{soil}) - \delta^{13}C(\text{pm})}{\delta^{13}C(\text{new}) - \delta^{13}C(\text{pm})} \times 100 \quad (8)$$

where $\delta^{13}C(\text{soil})$, $\delta^{13}C(\text{pm})$, and $\delta^{13}C(\text{new})$ represent the stable C isotopic composition of the carbonate in the bulk soil, parent material, and the pure PC, respectively.

Stable isotope ratios of $^{13}C/^{12}C$ and $^{18}O/^{16}O$ are used to study carbonate dissolution, transportation, and precipitation processes and rates.^[17] They provide additional records of past environments that include shifts in vegetation, climate, and atmospheric circulation.^[18,19] As a result, studies of carbonate isotope chemistry have become an important component of paleoecology and global change research. Substantial variations in the ratio of these two isotopes are important to trace and quantify sources, sinks, and flux rates within the C cycle.^[20]

RATE OF PC FORMATION

A simulation model, CALDEP, was developed by Marion and Schlesinger^[21] to predict the amount of PC deposition

Fig. 2 Scanning electron micrographs of PC from the inner (A) and outer (B) layers of a carbonate pendant.

Table 1 Rates of PC deposition in the soils of the southwestern deserts of the United States and Saskatchewan.

Location	Rate of deposition (g CaCO ₃ m ⁻² yr ⁻¹)	Location	Rate of deposition (g CaCO ₃ m ⁻² yr ⁻¹)
Nevada, Mormon Mesa	1.73–10.85	Brown soils, SK, Canada	8.3
California, Whipple Mountain alluvium	1.0	Dark brown soils, SK, Canada	11.4
Arizona, Avra Valley	3.87–5.67	Black soils, SK, Canada	11.2
New Mexico, Rio Grande Valley	1.0–12.0		
New Mexico, Rio Grande Valley	2.2–5.1		

Source: From Schlesinger^[23] and Landi.^[24]

in soils (caliche) of the deserts of the Southwestern United States. The model assumed that most PC formed under climates with cool and wet winters during the Pleistocene. The predicted CaCO₃ deposition rate was 1–5 g m⁻² yr⁻¹ (0.12–0.6 g C m⁻² yr⁻¹) with an input of CaCO₃ as atmospheric dust of 0.51 g m⁻² yr⁻¹. The model also predicted that an increase in rainfall resulted in an increase in CaCO₃ precipitation.

The rate of PC accumulation calculated by Machette^[22] for non-calcareous parent materials ranges from 1.4 to 5.1 g m⁻² yr⁻¹ (0.17–0.61 g C m⁻² yr⁻¹) for three areas in New Mexico and Utah. Using ¹⁴C, ²³⁰Th, and ²³⁴U dates of calcic horizons of Aridisols in the Mojave Desert, Schlesinger^[23] has calculated the rate of deposition of PC to be between 1.0 and 3.5 g CaCO₃ m⁻² yr⁻¹ (0.12–0.42 g C m⁻² yr⁻¹). In semiarid Saskatchewan, the rate ranges between 8.3 and 11.4 g CaCO₃ m⁻² yr⁻¹ (0.99–1.34 g C m⁻² yr⁻¹; Table 1). The rate increases with increasing precipitation.

CONCLUSION

Secondary or PCs are those that are formed through the processes responsible for the soil development. The PC is an important part of the global carbon cycle. Global estimates are far from complete. The stable isotope technique is used to calculate the amount and rate of secondary carbonates. The rate of secondary carbonate formation in arid regions of California, Arizona, and Mexico states in the United States ranges from 1 to 5 g C m⁻² yr⁻¹, and it increases up to 11.2 g C m⁻² yr⁻¹ with increasing precipitation in semiarid Saskatchewan, Canada. Studies from other parts of the world are needed to make a reliable estimate of global PC.

Carbonates: Water and

Michael Duniway

Jornada Experimental Range, U.S. Department of Agriculture—Agricultural Research Service (USDA-ARS), Las Cruces, New Mexico, U.S.A.

Abstract

The soil carbonates occurring as solidified masses or dispersed particles can alter the soil water dynamics compared to that expected from noncarbonate soil properties. Carbonate minerals in the soil can be derived from high-carbonate parent material, additions in the form of carbonate mineral containing rain or dust, high-carbonate groundwater, and formed *in situ* as secondary minerals. Soil carbonates found in the fine earth fraction are predominately derived from precipitates and are usually of the clay and silt size classes. Carbonate coarse fragments can be derived from carbonate parent material detritus or from pedogenic sources such as nodules and petrocalcic rubble. Parts of the profile can be continuously indurated with carbonates due to either the high-carbonate bedrock or the formation of a petrocalcic horizon. The accumulation of dispersed soil carbonates appears to increase the available water-holding capacity (AWHC) in coarse-textured soils and some fine-textured soils. Due to the relatively high AWHC of carbonate rock-like material ($0.03\text{--}0.22\text{ m}^3\text{ m}^{-3}$), soil profile AWHC will likely be underestimated if fragments of indurated carbonate material or clasts of carbonate parent material are ignored. The high water-holding capacity of petrocalcic horizons, high-carbonate bedrock, and the presence of water within these cemented soil horizons indicate their potential importance as a plant's water source, especially during dry periods.

INTRODUCTION

Carbonate minerals occur commonly in soils and have long been recognized for their importance in soil nutrient availability and soil structure. The soil carbonates occurring as solidified masses or dispersed particles, however, can alter the soil water dynamics compared to that expected from the noncarbonate soil properties. Carbonate minerals in the soil can be derived from high-carbonate parent material, additions in the form of carbonate mineral containing rain or dust, high-carbonate groundwater, and formed *in situ* as secondary minerals. Although many carbonate minerals occur, calcite (calcium carbonate) accounts for the vast majority of carbonates in soils (see the entry *Inorganic Carbon: Composition and Formation*, p. 1199) and will herein be referred to as carbonates. Soil carbonates in the fine earth fraction are predominately derived from precipitates and are usually of the clay and silt size classes.^[1] Carbonate coarse fragments can be derived from carbonate parent material detritus or from pedogenic sources such as nodules and petrocalcic rubble. Parts of the profile can be continuously indurated with carbonates due to either high-carbonate bedrock or the formation of a petrocalcic horizon. All sizes and morphologies of soil carbonates have important implications in soil water availability and dynamics.^[2–6]

FORMATION

Whether the source is carbonate dust, rain, parent material, or weathering of primary minerals, carbonate minerals tend

to move down the soil profile in solution. Because carbonates can be leached out of the soil profile, soils with the greatest amounts of carbonate occur in areas where evapotranspiration losses exceed precipitation, including arid, semiarid, and subhumid climates (see the entry *Inorganic Carbon: Composition and Formation*, p. 1199).

In poorly leached soils, carbonate minerals precipitate where the soil solution dries and reactants are concentrated. Fine carbonate crystals ($\sim 2\text{--}10\text{ }\mu\text{m}$) initially precipitate along roots, fungal hyphae, and soil particle surfaces and progressively fill soil pores.^[7] With sufficient time, carbonates can completely plug soil pores, producing an indurated horizon and a distinct laminar carbonate cap (petrocalcic horizon). The formation of laminar morphology is attributed to the restriction of downward soil water movement and the precipitation of carbonates in the accumulated soil water. Petrocalcic horizons are characterized by high densities and bulk carbonate contents.^[3]

DISPERSED CARBONATES

The accumulation of soil carbonates generally increases the available water-holding capacity (AWHC) of coarse-textured soils but has little effect or reduces the AWHC of fine-textured soils. Based on micromorphology, plugging of pores with carbonates can change a coarse-textured soil from a matrix of large pores to one dominated by fine pores.^[7] Soil water release curves (SWRCs) measured for a high-carbonate calcic horizon resemble those of soils with higher clay contents than those of soils with the

Fig. 1 SWRCs of nonindurated high-carbonate soils (black) and of soils after carbonates were removed (gray). Gray and black lines in the same pattern are SWRCs of the same samples with and without carbonates, respectively. Carbonate content and soil textural class with and without carbonates are noted in the legend. **Source:** Adapted from Baumhardt & Lascano^[2] and Stakman & Bishay.^[8]

noncarbonate horizon texture (sandy clay loam; Fig. 1).^[2] Conversely, Stakman and Bishay^[8] found soil carbonates to reduce the amount of water held across all potentials, except in very coarse-textured soils (Fig. 1). The carbonate content was found to be negatively correlated with soil water retained at water potentials near saturation (-1 and -10 kPa) in a predictive model developed for high-carbonate glacial till subsoils.^[9]

Extensive water extraction by several row crop species from a strong calcic horizon has been documented.^[10] For some species, plant water availability and specific root water-uptake rates were higher in the calcic horizon than in the overlying soil layers. Similarly, fairly high hydraulic conductivity values have been reported for calcic horizons, and values that are larger than would be expected based on the texture alone.^[2] Despite the importance of soil carbonates for soil water-holding capacity and dynamics, methods for measuring soil particle size distribution, the soil property often used to predict soil water-holding capacity and dynamics, often recommend pretreatment to remove carbonates.

INDURATED CARBONATE NODULES AND CLASTS

The water-holding capacity of carbonate nodules, fragments, and parent material clasts has been found to be

significant^[3,4] and often higher than that of other coarse fragments, either pedogenic or those inherited from the parent material.^[11–14] AWHC for calcareous rock fragments is generally lower (0.03 – 0.14 $\text{m}^3 \text{m}^{-3}$)^[4] than that reported for fragments from a petrocalcic horizon (0.04 – 0.22 $\text{m}^3 \text{m}^{-3}$).^[3] Limestone clast SWRCs are similar to those of laminar morphology petrocalcic material of similar bulk densities (Fig. 2). Petrocalcic fragments of plugged morphology, which are cemented by carbonates within the original soil matrix, have much higher AWHC than either laminar morphologies or limestone materials. Because plugged morphologies of petrocalcic horizons contain some of the noncarbonate soil matrix, bulk density as well as carbonate content appears to be important for water retention (Fig. 2).^[3] Soil volume occupied by clasts, either carbonate or otherwise, however, is almost always excluded when quantifying soil profile available water and soil water-holding capacity.

CARBONATE BEDROCK AND PETROCALCIC HORIZONS

Limestone bedrock and petrocalcic horizons have been shown to contain significant amounts of water that is potentially available to plants.^[5,6] In many soils, these layers occur within the rooting depths of deep-rooted shrubs and in some areas within the rooting zone of grasses and row crops. Although carbonate-cemented soil horizons appear to be water restricting, there is evidence that these horizons

Fig. 2 SWRCs for petrocalcic horizon material and limestone clasts from calcareous glacial till soils. Bulk density and carbonate content are noted in the legend.

Source: Adapted from Duniway, Herrick, et al.^[3] and Cousin & Nicoullaud.^[4]

do absorb soil moisture. Petrocalcic horizons can rapidly absorb and retain large volumes of soil water with a measured field capacity of up to $0.36 \text{ m}^3 \text{ m}^{-3}$.^[6] When compared with similar depths in deep sandy soils, shallow petrocalcic horizons (~0.5 m deep) in sandy soils have been shown to absorb and retain larger quantities of winter and summer rains and retain water at plant-available tensions more consistently.^[6] Following a wet summer, the petrocalcic horizon monitored retained very high plant-available water contents (16–18% volumetric) through early spring of the following year, more than double the amount retained by similar depths in the deep sandy soil.^[6] Native perennial grasses growing on similar petrocalcic soil in a semiarid region were found to have lower mortality rates than grasses growing on coarse-textured soils lacking shallow petrocalcic horizons.^[15] Similarly, relatively high soil water contents have been reported for limestone bedrock in a dry tropical forest.^[5] In the same system, roots of native tree species were observed within the softer limestone along with isotopic evidence of utilization of the contained water.

CONCLUSION

High-carbonate soil horizons are common in arid, semiarid, and subhumid regions around the world. Understanding soil AWHC and dynamics is of particular importance in these dry climates. The accumulation of soil carbonates appears to increase AWHC and improve soil water relations in coarse-textured soils^[3,6,8] and some fine-textured soils.^[2] Soil profile AWHC will likely be underestimated if fragments of indurated carbonate material or clasts of carbonate parent material are ignored.^[3,4] In coarse-textured soils, the water retention provided by the fine porosity in these fragments could be of particular importance during extended dry periods. Similarly, the water-holding capacity of petrocalcic horizons and high-carbonate bedrock indicates their potential importance as a plant's water source, especially during drought. Retention properties of these high-carbonate layers do limit the downward loss of soil water. Instead of posing an insurmountable obstacle to soil water movement as generally believed, however, carbonate-cemented soils and parent materials appear to potentially function as a reservoir of water in some systems. Water in some of these denser materials could be made available to plants through either bulk flow to roots in contact with the outer surface or mycorrhizal relationships. More work is needed to further understand the importance of water contained in carbonate rock and rock-like material and the importance of this water for existing and potential plant communities.

Care of Soil

Delia C. Catacutan

Global Research Program, World Agroforestry Center, Malaybalay City, the Philippines

Abstract

The term “soil care” reflects the human and social dimension of soil management, based on the growing realization that the problems of soil degradation cannot only be single-handedly addressed by technical solutions but also through engagement of multiple stakeholders, whose day-to-day decisions affect the health of the soil. From its roots in Australia, landcare is widely adopted as a multistakeholder approach to integrated natural resource management, where multitudes of farmers and land users work together to care for the land and improve their livelihoods. Landcare has shown that a “land ethic” is fundamental to successful conservation efforts.

INTRODUCTION

“Soil” is one, if not the most important, input to production. With constantly increasing demand for production of food and fiber and environmental services, “care of soil” has never been urgent. Soil degradation is a physical process; hence, conventional soil management focused on technological solutions. However, the underlying causes of soil degradation are deeply rooted in complex sociocultural, economic, and political contexts.^[1] Therefore, institutional and policy solutions are equally pressing as the technical solutions to soil degradation.

The term “soil care” resonates the human and social dimension of soil management, based on the growing realization among scientists, practitioners, scholars, advocates, policy makers, local communities, and most importantly farmers, that the earth’s soil is not just a biophysical unit, requiring discrete management techniques, but largely a social unit where multiple decisions of multiple stakeholders have a direct impact on its health. As part of an integrated natural resource management (NRM) strategy, “care of soil” requires a nuanced process of incorporating complex aspects of soil management into a sustainable system that meets the explicit goals of production, profitability, and risk reduction by multiple stakeholders. This means that soil care is no longer the exclusive domain of soil scientists; in general, NRM calls for “integration” across disciplines and objectives, scales, stakeholders, structures, and components.^[2]

This entry discusses soil care from a social perspective. Landcare is presented as a multistakeholder approach to NRM. It concludes that the bottom line of soil care is a “land ethic” developed among stakeholders within and across sectors and levels of society.

MULTISTAKEHOLDER ENGAGEMENT IN SOIL CARE

Soil degradation is a physical process, but soil management is largely a social process. As a key natural resource, soil health is influenced by the day-to-day management decisions of large numbers of different types of stakeholders at various scales.^[1,3] These stakeholders often (e.g., small and large holder farmers, policy makers, managers, administrators, businesses, scientists, communities, other economic and social sectors, etc.) have contrasting objectives, based on their specific circumstances and positions in society.^[3] For farmers, trade and price policies are crucial because their decisions are commonly responsive to relative prices and to price variability.^[4] Because of variability of production inputs (e.g., soil fertility) and volatility of outputs, the farmers constantly struggle to meet their production goals while managing soil fertility, and governments are stifling its ability to enforce regulatory measures on land use. As soil fertility drops, productivity declines, and incomes fall, poor farmers are being blamed for environmental degradation.^[1,5] This is unforgiving, given the lack of incentives to farmer adoption of conservation technologies due to the cycle of poverty and skewed patterns of economic development.^[1,6,7]

The whole gamut of soil management is complex, requiring active involvement of various stakeholders. However, multiple stakeholder engagement is not straightforward. Many of the difficulties experienced in engaging stakeholders are the result of poor policy analysis and program design.^[1,8] The underlying issue is that many economies employ a reductionist approach with institutions specializing in either production or conservation, or regulation and control.^[1] This structural constraint reduces the chances for innovation and integration. Furthermore,

stakeholder decisions are often formulated based on political considerations; hence, engaging multiple stakeholders in soil care is a formidable task.^[3]

The Landcare Approach

Landcare is a multistakeholder approach that employs innovative solutions to NRM challenges, linking farmers with the broader community and helping them influence resource policy.^[1,9] It centers on formation of landcare groups, supported to varying degrees through partnerships with government, non-government, and private sector stakeholders.^[6,9,10] Landcare groups are involved in farm care, catchment care, vegetation and coastal management, property planning, capacity building and research, and resource generation for livelihood financing.^[1]

Beginning in mid-1980s, the growth of Australian Landcare has been explosive, with over 4000 landcare groups formed.^[1,6] Bipartisan political support and the broad popular appeal of landcare contributed to success, but the presence of catastrophic land degradation across vast swathes of Australia triggered the landcare movement.^[6] Australian soils are declining with annual soil loss averaging between 5 and 10 tons ha⁻¹, with sugarcane as the most erosive crop (150 tons ha⁻¹ yr⁻¹).^[11] The country is basically short of good soils, with less than 300,000 km² (less than 4%) classified as good or very good, in terms of quality for broadscale cropping.^[12] However, significant progress has been achieved through landcare, and it has been highlighted as part of the fabric for achieving sustainable ecosystems.^[6]

Some 17 countries or multilateral organizations in the Pacific, Africa, America, Europe, the United Kingdom, and Southeast Asia are either independently implementing landcare programs or receiving limited support to initiate them.^[3] The genesis of landcare in these countries was different, evolving through different pathways, but the problems that landcare groups are trying to address are similar,

adhering to the same principle, which is enriching human and social capital to mobilize local action, to reverse land degradation and improve rural livelihoods.^[1] Regardless of differences in circumstances, the essential requirements to facilitate this process are also common, i.e., a good balance between community efforts and public-private partnerships.

Evidence suggests that landcare has significantly contributed to improving NRM and livelihood outcomes in areas where it is active (Fig. 1). Landcare associations around the world have developed more resilient capacities to transform farming systems to mitigate and adapt to climate change through practices that increase carbon sequestration.^[1] In the Philippines, landcare provides a coping mechanism for communities to achieve resiliency.^[13] In Uganda, Australia, New Zealand, Germany, Iceland, and South Africa, landcare associations are actively implementing sustainable farming and catchment-wide management projects.^[1]

A distinctive strength of landcare is the involvement of research and development (R&D) institutions. In New Zealand, landcare is implemented by the NZ Landcare Trust, a research-based non-governmental organization (NGO), while the World Agroforestry Centre (International Centre for Research in Agroforestry—ICRAF) pioneered landcare research in the Philippines and in Eastern Africa, and in the United States, Virginia Tech University facilitates landcare R&D linkages. Landcare has thus demonstrated a mechanism for linking scientific knowledge with actions from the local to the global level.^[1]

Building a Land Ethic

There are many aspects, with which to identify the success of landcare. Among them is improved human and social capital for farmers to apply conservation technologies and stakeholder engagement in decision making.^[1] The high level of community participation indicates profound

Fig. 1 Annual and cumulative adoption of contour hedgerows using natural vegetative strips (NVSS) and agroforestry practices in Claveria, Misamis Oriental, in the southern Philippines. Rapid adoption of NVS and agroforestry was observed beginning in 1996, when farmers had started to actively disseminate the technology throughout the municipality. Rapid increase in adoption was unprecedented in Claveria despite previous efforts of other agencies that promoted conservation farming in the Philippine uplands. Farmers were technically assisted by local agricultural technicians and ICRAF researchers. This marked the beginning of landcare in the Philippines.

Source: From ICRAF Philippines' database.

cultural changes in people's understanding on the land and their relationship with their environments.^[6] Stakeholder engagement across geographic scales (farms–catchments); sectors and structures (farmer–government agencies–NGO–business–R&D); and disciplines, interests, and objectives (farm conservation–water management–research–capacity building–livelihood) fostered the emergence of a “land ethic” based on the spirit of stewardship and volunteerism, complimented with various types of support and incentives.^[14]

CONCLUSION

Care of soil has never been resolute than in the past decades. The greatest challenge in human history has been developing management systems that meet present and future needs of food and fiber and ecosystem services. Integrating soil science solutions across other disciplines has become more important, not only because the soil is a complex biophysical unit but also because it is a dynamic social unit when all factors of utilization are considered. Multiple sources of knowledge are needed to draw multiple solutions, through engagement of different types of stakeholders at various scales. The landcare experience has shown that reversing land degradation and broad-level NRM outcomes can only be achieved through building a land ethic among the global community.

ACKNOWLEDGMENTS

The author is grateful to many landcare colleagues for sharing their experiences, on which this entry is based. Special acknowledgment is due to the Iceland Soil Conservation Service for providing the opportunity to share the landcare experience at the 2007 Global Forum on Soils, Society, and Global Change, with which this topic was deemed relevant to soil science and to the Soil Science Encyclopedia.

Cerrado

Igo F. Lepsch

Soil Science Department, Luiz de Queiroz College of Agriculture (USP-ESALQ),
Piracicaba, Brazil

Abstract

The Cerrado is a South American tropical savanna ecosystem that originally covered about two million square kilometers. The major areas are on in Central Brazil where annual rainfall is between 1100 and 1600 mm concentrated in a period of 6 or 7 months. About 45% of the Cerrado's soils are the well-drained Oxisols (also named as Ferralsols in the FAO soil map of the world and latossolos in the Brazilian soil classification system) occurring either on extensive, almost flat, tableland tops, or on gently undulating low hill surfaces. Other Cerrado's soils are the Ultisols (16%), Entisols (20%), and Cambisols (3%). The Oxisols were developed on stable geomorphic surfaces under thick layers (more than 2 m) of pre-weathered parent materials. Their high contents of aluminum and iron oxides made them very permeable and with good physical properties for mechanized agriculture even with high amounts of clay. These tropical, naturally nutrient-poor, deep acid soils with low cation exchange capacity were long considered unsuitable for crop production. However, research in soil science in Brazil has provided knowledge for the utilization of the Cerrado's vast areas of Oxisols as extremely productive agricultural lands. This achievement, in the last years, is considered the world's single largest increase in farmland since the settlement of Midwestern United States that began in 1850.

INTRODUCTION

The Cerrado biome is a kind of edaphic tropical savannah which, before being occupied by intensive agriculture, covered approximately two million square kilometers (Fig. 1). It is typical of the high plateaus that preserve old geomorphic surfaces in central Brazil where vegetation has evolved to survive for millions of years adapting to long dry periods and having nutrient-poor and very acidic soil conditions. Its flora is considered to be the richest in biodiversity among the world's savannahs.^[1] Almost half of the land originally covered by the Cerrado vegetation has been transformed into cultivated pastures and extensive crops.

CLIMATE, VEGETATION, AND GEOLOGY

The Cerrado climate is limited to two dominant seasons throughout the year—wet and dry, with the dry season during the southern winter (approximately April–September). Annual temperatures average between 22°C and 27°C, and average precipitation is between 800 and 2000 mm for over 90% of the area.^[1]

This large-scale vegetal province possesses distinctive flora with hundreds of endemic species. There is much evidence that the Cerrado biome has existed in prototypical form since the Tertiary period.^[1,2] During this time, the plant species of the Cerrado have evolved under alternating

conditions of subhumid and semiarid climates and on highly weathered, acidic, and extremely nutrient-poor soils.^[2] The vegetation physiognomies include forest savannah (*cerradão*), wooded savannah (*cerrado strictu sensu*), park savannah (*campo cerrado*), gramineous-woody savannah (*campo sujo*), and grasslands (*campo limpo*). Some gallery forests around wetlands are also included. The *cerrado strictu sensu* is a mosaic of sparse vegetation of trees and shrubs with twisted trunks and crooked or irregular branching, often possessing rigid leaves and thick wrinkled or cracked barks; the herbaceous stratum is usually short hard grasses.^[3]

The parent rocks of the Cerrado soils are mostly pre-Cambrian rocks of the Guiana and Brazilian shields (gneisses, schists, and granites) and Paleozoic and Mesozoic basalts, sandstones, and shales. However, the parent material of most of the present soils was weathered on former non-glaciated land surfaces and redistributed during many episodes of erosion, especially during the shifting from humid to semiarid climates (that coincided with interglacial and glacial periods of lower latitudes) of early Cenozoic time.^[4] As a result, few micas, feldspars, apatites, and other weatherable minerals containing potassium (K), calcium (Ca), magnesium (Mg), or phosphorus (P) remained, having long since been dissolved while in previous locations and/or during transport. Most present-day soils formed in such material that had been exposed to many cycles of weathering, erosion, and deposition; almost no nutrient-bearing minerals were present and sand-sized

Fig. 1 Geographic location of the Cerrado region in Brazil.

quartz and clay-sized iron and aluminum oxides, as well as, kaolinite are the dominant primary minerals remaining in the parent material within which the present soils have formed.^[5,6]

PRINCIPAL SOILS OF THE CERRADO

The principal soils of the Cerrado are represented by the well-drained “non-plinthic” Oxisols,^[7] also named Ferralsols in the Food and Agriculture Organization (FAO) soil map of the world^[8] and Latossolos in the Brazilian Soil Classification System,^[9] and they comprise about 45% of the Cerrado’s area and are well-drained soils without iron concretions, occurring either on the extensive, almost flat, tableland tops (locally called “chapadas”) or on gently undulating low hill surfaces. These Oxisols are deep and well drained presenting no physical barriers to root development. Other Cerrado’s soils are classified^[7] as Ultisols (16%), Entisols (20%), and Cambisols (3%). The Entisols are either very sandy (Quartzpsamments) or shallow soils. About 9% of the area includes soils rich in soft (plinthite) or hard (petroplinthite) iron concretions (the former called “laterite”^[5,6]).

General soil landscape studies involving the Cerrado soils were reported by Feuer,^[10] Queiroz Neto,^[2] and Lepsch and Buol.^[6]

SOIL-RELATED CONSTRAINTS TO BIOMASS PRODUCTION

Soils that support cerrado vegetation are considered as some of the most chemically infertile in the world. Because of the nutrient-poor soils, the natural vegetation of the gramineous-woody Cerrado strata is so poor in nutrients that it was considered marginal even for

extensive domestic cattle pasture. There are no accounts indicating that herds of native large mammals are present in similar appearing but in nutrient-rich and water-stressed savannahs of Africa and prairies of Midwestern U.S. prior to European settlement. In the Cerrado, domestic cattle often died from broken bones after grazing only Ca- and P-deficient grasses, and ranchers came to refer to Cerrado as a place to lose cattle rather than graze cattle.^[5]

The highly weathered latossolos^[9] of the Cerrado are devoid of the plant macronutrients such as Ca, Mg, K, and P as well as some micronutrients. The association of kaolinitic clays with iron and aluminum oxides has the ability to adsorb P in forms unavailable to plants. However, this same mineral assemblage forms a strong fine and very fine granular structure often called “pseudosand.” The result is that very small voids within the granules retain water at high tension, and the large voids between the granules allow water to rapidly percolate under the force of gravity. This accounts for the characteristic of these latossolos—even with high amounts of clay, they are very permeable and have good physical properties such as good tilth capability.^[11]

MANAGEMENT OPTIONS FOR SUSTAINABLE LAND USE

Although the Latossolos originally under Cerrado vegetation can be considered as some of the most chemically infertile in the world, their cropped areas are among one of the most productive lands in the world. In the year 2014, about 14 million hectares were set into annual crops and 60 million hectares into improved pastures. Before 1960, very little farming or intensive grazing took place, and with a very low population density, the land purchase costs were cheap. Among the most important soil factors contributing to low yields are Ca, P deficiency, aluminum toxicity, and low soil water storage capacity.^[12]

Field experiments testing recommendations for liming and fertilizers were established shortly after the new capital, Brasilia, was built in the center of the Cerrado region, in the 1960s.^[5,12] Progressively, experienced farmers from south of Brazil moved into the area, bringing commercial farming practices and grain production based on these research findings.

The uniform temperatures and the dry season allowed for ideal conditions for sowing and harvesting the grain over extended periods of time, resulting in maximum efficiency of machinery operations and reducing time and cost to dry the harvested grain. In these lands, two cycles of crops per year are possible, even without irrigation if no-till systems—now a common practice—are used. Much of the production of grain and meat taking place there today is the result of the scientific understanding that some of the chemical properties of the soil had to be changed before

grain production and cattle grazing could take place.^[12] The two primary changes needed were to provide plant-available P and the replacement of extractable aluminum with Ca on the cation exchange capacity (CEC) sites in the soil.^[5,12]

The amount of surface area on the iron oxides present in high amounts in topsoil was responsible for adsorbing large amounts of P added as fertilizer. Field studies determined that initial applications of lime and relatively great amounts of P sustained maximum grain yields through several years^[5] and thus are economically feasible. The aluminum toxicity and Ca and Mg deficiency can be overcome with modest lime applications. Also, Ca when supplied as gypsum has been found to move downward more rapidly than calcium carbonate forms. With continued applications of lime and gypsum, the naturally Ca deficient and aluminum toxic subsoil will acquire exchangeable Ca below the depth of cultivation and provide for deeper rooting and thus buffer crops better from drought damage.^[5,12]

Modern soil science finds an example of the high yields obtained in the deep, highly weathered, and low CEC soils of the Cerrado that proves that vast tropical areas of previously uncultivated soil, long considered unsuitable for human food production, can be transformed into highly productive agricultural land. Naturally, acid soils with high contents of aluminum and iron oxides and low CEC values and organic matter contents, long considered insurmountable obstacles to crop production in tropical latitudes, could be extremely productive. This phenomenal achievement over a span of less than 50 years is the world's single largest increase in farmland since the settlement of mid-west U.S. that began in 1850 and has been hailed as a far reaching achievement and milestone in agricultural science.^[13]

Chemical Composition

Goro Uehara

Department of Agronomy and Soil Science, University of Hawaii, Honolulu, Hawaii, U.S.A.

Abstract

Soil chemical composition is the product of the interactions of climate, topography, and biota operating over geologic time on a parent rock that is open to gains and losses of matter. Physical disintegration and chemical weathering transform existing unstable minerals into secondary or pedogenic minerals that may differ in kind and composition with depth in the profile. Soil chemical composition is important only in so far as it can be related to the behavior and performance of soils.

INTRODUCTION

Every student of soil science learns to recognize and appreciate soil differences and to understand how these differences affect soil behavior and performance. Soils can differ in particle size distribution or texture, in the way the individual particles are arranged and cemented to form compound particles or peds, in the amount and type of organic matter and in the mineralogy of the inorganic particles. Variations in any of the above will determine whether a soil will behave as a sponge to absorb and hold water, as a sieve and filter to purify water as it flows through the soil, or as a plastic or elastic rheologic body to withstand the pressure of a tractor wheel. How a soil behaves will, in turn, determine whether it will perform well as a soybean field, building foundation, playground, or waste disposal site.

The soil differences just described generally go hand in hand with differences in chemical composition. A soil that is 95% quartz sand or silicon dioxide will clearly behave and perform differently in many ways from another that is 95% coral sand or calcium (Ca) carbonate. These two soils would in turn behave and perform very differently from an organic soil, and all three would again differ greatly from a tropical soil rich in iron oxides. How do soils with such diverse chemical makeup originate? The purpose of this entry is to summarize the biogeochemical processes and factors that lead to differences in the chemical composition of soils.

SOIL-FORMING PROCESSES

Changes in the chemical composition of the rock and the soil that forms from it are the result of four soil-forming processes: transformations, translocations, additions, and losses.

Transformations

The process of weathering takes place because the minerals that make up the rock are thermodynamically unstable under the conditions prevailing at the site. Under these conditions, minerals exposed to the elements undergo hydration, hydrolysis, dissolution, and oxidation–reduction. Ions that go into solution, if not washed out to sea, seek new equilibria to form secondary or pedogenic minerals.^[1,2] In dry regions, one of the first secondary minerals to form is calcite. As rainfall and leaching intensity increase, sodium (Na), potassium (K), Ca, and magnesium (Mg) leave the system and secondary, layered aluminosilicates become more prominent. And with time and intense leaching, desilication transforms even the secondary silicates to metal oxides and hydrated oxides. It is no accident that bauxite deposits are more common in the tropics than elsewhere in the world. An example of concentration of aluminum through weathering is illustrated by the data in [Table 1](#).

Translocations

Termites, earthworms, and burrowing animals move huge quantities of soil material to the surface. Surface soil materials can also fall between cracks in soils that shrink and fracture when dried. Repeated wetting and drying result in churning and inversion of the soil creating surface patterns called gilgai. These inverting soils are aptly named Vertisols. Particles suspended in water can also be transported to greater depth and deposited on walls of water-conducting pores. The wall coatings are called argillans or clay skins and can significantly increase the clay content of the subsoil horizons called argillic horizons.

Additions

The addition of water to soils is taken for granted, but water enables most other soil processes to occur. Water is

necessary for life and the production of soil organic matter. Weathering that may begin as a geochemical reaction soon turns into a biogeochemical process with the first appearance of lichens on rock surfaces. Additions of dissolved gases and electrolytes play critical roles in soil formation. Rainfall also scrubs particulate matter from the atmosphere. Tropospheric dust from Asia containing quartz and mica is deposited over the northern Pacific, but its concentration on land is highly dependent on rainfall.^[3] Close to their sources, aerosolic dusts can form thick loess deposits.

Losses

One soil's loss can be another soil's gain. Wind erosion that generates aerosolic dust exposes underlying materials to the elements to renew the weathering processes. Landslides and water erosion do the same and create new parent material downstream.

Less obvious soil losses occur through solution in drainage waters as evidenced by the salty sea. Desilication or leaching of silica from soils into streams and oceans is evident in the data presented in Table 1. Less obvious are gaseous losses through microbial activity. Carbon dioxide (CO₂), methane, and nitrous oxide fluxes into and out of

soil are measured with renewed interest because of their role as greenhouse gases.

SOIL-FORMING FACTORS

On a geologic timescale, soils are transient bodies on the landscape. What we see today may have little resemblance to what was there in the beginning and what will remain in the end. The birth of a soil might begin with the solidification of molten lava to form solid rock or the exposure of seafloor from geologic uplift. The end could come with a landslide or during accelerated soil erosion on a cultivated hillside. But between beginning and end, major chemical transformation usually occurs so that the end product would be unrecognizable from the parent rock. In addition to time and the parent rock, three additional factors operate over time to produce differences in the soil chemical composition.^[5] These three factors are climate, topography, and biota. All five of these factors have been discussed earlier, but will now be covered with emphasis on soil chemical composition.

Parent Rock

One would expect the chemical composition of the parent rock to have a significant effect on the chemical

composition of the soil that forms from it. It does—but the departure from initial rock composition is generally greater than one would expect (see Table 1). This departure from parent rock composition occurs because soils are open systems that gain new substances and gradually lose their original minerals primarily through erosion, dissolution, and leaching. Rock-forming minerals, however, differ in their susceptibility to weathering.^[6] Acid igneous rocks containing K feldspars, muscovite, and quartz tend to be more resistant to weathering than basic igneous rocks containing plagioclase feldspars, biotite, and amphiboles. Igneous rock erupted as lava or tefra having identical chemical compositions can and will most likely weather into very different chemical end products. Tefra consisting mainly of glassy particles tends to weather more rapidly than lava rock and to develop into soils that fall in the unique Andisol soil order.

Time

Mohr,^[7] a Dutch scientist investigating soils in Indonesia during colonial times marveled at the soils he found there, and to organize his findings, categorized soils as being juvenile, mature, or senile. Mohr’s juvenile soils still retained features of their parent rock and had not yet developed distinct features that set them apart from other soils. The mature soils were those favored by farmers. In mature soils, the parent rock had been weathered to clay, but nutrient elements such as Ca, Mg, K, and phosphorus were still plentiful. But what intrigued Mohr most were the senile soils. Prolonged weathering under warm and humid conditions had stripped the soils of life-sustaining nutrients and rendered them unsuitable for farming. What remained on the landscape were the insoluble residues of iron and aluminum oxides along with resistant rock-forming minerals such as quartz. Senile soils are more likely to occur near the equator because soil changes faster under warm tropical climates.

Climate

The influences of climate on soil chemical composition can best be observed along steep climate gradients located on a single parent rock of known geologic age. Such conditions occur on the Hawaiian Islands, and researchers are taking advantage of them to study the role of rock age,^[8] Island age,^[9–11] and climate.^[12] The islands offer temperatures associated with balmy beaches to snow-capped mountains and precipitation that range from rainforests to deserts, all compressed in a small area. A combination of steep rainfall gradient, warm tropical climate, and a basaltic parent rock containing easily weatherable minerals contributes to large soil chemical differences over short distances and in a relatively short period. The data in Tables 2 and 3

Table 2 Effect of climate on chemical composition of two soils developed from volcanic ash: (A) in a dry zone (mean annual rainfall: 800 mm; mean annual temperature 17°C) and (B) wet zone (mean annual rainfall: 3400 mm; mean annual temperature: 18°C).

illustrate how differences in climate can produce soils of very different compositions and properties from identical parent rock.

Topography

Soil composition is affected by topography primarily through drainage and hydrology. Soil in depressions tend to be wetter, cooler, and richer in organic matter, clay, and bases. These differences occur naturally but are amplified by cultivation. Soils on high points on the landscape tend to be net losers of fine particles and dissolved matter, whereas bottom lands tend to be net accumulators of the same. Soils in between form a toposequence of composition that is repeated in a predictable pattern over the landscape. Topography and drainage control wetness, oxygen supply, oxidation–reduction potential, leaching, and pore water composition. All of the above affect biological diversity and activity and the biogeochemistry of the system. Soil chemical compositional differences arising from topographic differences are the easiest to recognize in the landscape.

Biota

Plants clearly have an effect on mineral weathering.^[13] How different would a geochemically formed soil be from one formed biogeochemically? The presence or absence of organic matter would make a difference, but removing biota and organic matter from soils as we know them would not approximate one developed without living organisms. Not only do soil organisms such as termites and burrowing animals move huge quantities of soil material horizontally and vertically, but also plants produce residue that serves as an energy source for other organisms and recycles inorganic nutrients. The organic residues also act as cementing agents to hold clay particles into stable compound particles or peds. It is unlikely that a soil can withstand the erosive impact of raindrops without the cementing action of humus or the high infiltration rate soils acquired through the formation of large water-conducting pores

between large water-stable peds. Organic matter also chelates metal ions such as iron and aluminum and facilitate their downward movement, but it is their contribution to the physical and hydraulic properties of soils that biota influence long-term stability of soil composition.

CONCLUSIONS

Soil chemical composition is the product of the interactions of climate, topography, and biota operating over geologic time on a parent rock that is open to gains and losses of matter. Physical disintegration and chemical weathering transform existing unstable minerals into secondary or pedogenic minerals that may differ in kind and composition with depth in the profile. Soil chemical composition is important only in so far as it can be related to the behavior and performance of soils.

Chemisorption

N.J. Barrow

Mt. Claremont, Western Australia, Australia

Abstract

Many substances react with soil. Unless precipitation of ions from solution is involved, they initially react with the outside of soil particles in a process referred to as *adsorption*. When reaction continues and involves diffusion of the reactant into the interior of the soil particles, we use the more general word *sorption* to cover the whole process: adsorption plus diffusion. For some reactants, the attraction to the soil particles is largely electrical, e.g., the reaction of K^+ with a negatively charged surface. For other reactants, a strong inherent or chemical attraction is involved. This attraction may be so strong that ions overcome electrical repulsion and react with like-charged surfaces, e.g., the reaction of phosphate (P) ions with negatively charged surfaces. We use the word *chemisorption* to describe such reactions. Many nutrients such as P, borate, copper, and zinc are chemisorbed by soil, and this restricts their supply to plants. Similarly, many pollutants, including selenite, arsenate, mercury, and lead, are chemisorbed, and this slows their entry into the food chain.

SPECIFICITY AND SORPTION

It follows that chemisorption involves specificity. That is, an ion may be sorbed despite the presence of a large excess of some other like-charged ion in solution. An example is sorption of phosphate (P) from a solution containing chloride or nitrate. However, specificity does not always involve chemisorption. Preference may be a matter of valency or of differences in the tendency of ions to retain a sheath of water molecules. The terms also differ in that *specific absorption* describes an observation, whereas chemisorption requires some interpretation.

The strength of the chemical bond involved in chemisorption varies according to the ions involved. It therefore follows that specific adsorption is a graded property, with particular ions falling along a gradient of specificity.

CHEMICAL BONDING

For chemisorption to occur, there must be an attraction between the ion in solution and atoms on the surface of the soil particles. This attraction may show itself in other ways; e.g., both iron (Fe) and aluminum (Al) form low-solubility compounds with P. Similarly, metals, such as zinc (Zn), form hydroxides with low solubility. This has suggested that precipitates are important in the soil chemistry of such ions. However, discrete compounds are only formed when concentrated solutions leach out of fertilizer particles and have a limited life in soil. The ions eventually react with atoms, or groups of atoms, on the surface of soil particles: P and several other anions with Fe and Al atoms; and Zn and other metals with hydroxyls or with organic complexes.

SOIL COMPONENTS INVOLVED

Several kinds of soil particles may have appropriate groups of atoms on their surfaces. These include the edges of clay minerals, organic matter, and metal oxides. Fe oxides are the most widespread, with goethite being the most important and most frequently studied.

Even though chemisorption involves chemical bonds, these bonds must form between charged particles (ions) and charged surfaces. Two characteristics of the surfaces are important in this respect. One is that the charge on the surfaces varies with pH. In the case of metal oxides, this is because the metal atoms on the surface attempt to complete their electron shells by reacting with water molecules. These molecules lose or gain protons depending on the pH and the concentration of all ions in the solution in which reaction occurs. They are variable-charge surfaces. The charge is also variable in the spatial sense. Different particles, or different patches on the same particles, may carry different charge densities and therefore have different potentials. Direct evidence for this is that it is possible to measure both positive and negative charges in the one soil.

CHARACTERISTICS OF THE REACTING IONS

Two characteristics of the reacting ions are also important. First, many of the relevant acids have pK values in or near the range of soil pH values. Changes in pH therefore result in large changes in the ions present, with consequent effects on the reaction. Second, when the ions react with the surface, their charge must be conserved. Some of the charge is conveyed to the surface for reaction with P; the surface becomes more negative. The remainder of the charge is

returned to the solution for reaction with P; hydroxide ions may be desorbed (or protons adsorbed). The balance between these two options changes in a complex way with changes in pH and in the amount of sorption. Because the surface charge is consequently more negative, the affinity of the surface for more P ions decreases. Analogous effects occur for other ions.

This brief summary equips us to comprehend a great deal of the information on chemisorption; e.g., the Langmuir equation, although widely used to describe the relationship between sorption and concentration, is appropriate only in special circumstances. Soils do not provide one (or even two) uniform surfaces, and the feedback effect of the change in charge negates a basic assumption of this equation. A more realistic approach is to accept the range of surface characteristics and to apply a distribution to describe them. This distribution can be divided into slices, and a Langmuir-like equation that takes feedback into account can be applied to each slice. The net behavior is then given by the sum of the slices.

EXPLAINING THE EFFECTS OF CONCENTRATION

Consider how this model describes the most common observation in sorption studies: i.e., the relationship between sorption and concentration. In many studies, sorption curves are produced over a limited range of concentrations, about 100-fold. Over such a range, the Freundlich equation usually describes the data well. This means that a plot of log sorption against log concentration approximates a straight line. However, over a greater range, such as that illustrated in Fig. 1, curvature is obvious and is reproduced by the model outlined above. This curvature is inevitable because, at low concentrations, sorption is confined to the

Fig. 1 Sorption of P, Se(IV), and Se(VI) at pH values 5, 6, and 7, respectively, plotted on common axes. The concentrations were multiplied by the values in the table to give equivalent concentrations. Thus, at pH 5, the value for phosphate is 1; for Se(IV), 0.049; and for Se(VI), 0.0014.

Source: From Barrow.^[1]

most favored end of the spectrum of sites and is therefore on a nearly uniform set of sites. Further, because the amount of sorption is small, the feedback effect is insignificant. This is one of the unusual situations in which the Langmuir equation is appropriate. However, at very low concentrations, the form of the equation is such that sorption is virtually proportional to concentration. That means that on a log-log scale, the slope approaches unity. It is, therefore, much steeper than at higher concentrations.

EXPLAINING THE EFFECTS OF pH

Consider the interactions between pH and the concentration of the background solution on the sorption of some common inorganic anions (Fig. 2).

These interactions occur because there is an initial adsorption reaction of ions on a variable-charge surface. An increase in salt concentration increases the number of counter ions close to the surface and therefore changes the way that electric potential changes, as we move away from the surface. At any particular distance from the surface, an increase in salt concentration decreases the absolute value of the electric potential. For example, when a reaction is with a negatively charged surface, the potential becomes less negative and anion sorption increases. A convenient, though less precise, way of thinking about this is that an increase in the cation concentration near a negatively

Fig. 2 The effect of pH and background electrolyte concentration on the sorption of phosphate, Se(IV), and borate by a soil. In each case, sorption was measured at a solution concentration of 100 μ M. The lines were obtained by fitting the data into the model described in the text.

Source: From Barrow.^[1]

charged surface makes it easier for anions to react with the surface. The corollary is that, when increasing salt concentration increases the sorption of anions, the reacting surface must be negatively charged. In such cases, there must be a clear chemical component to sorption. By a similar argument, when sorption of anions is decreased by an increase in salt concentration, the reacting surface is positively charged. The results in Fig. 2, therefore, show that the reaction of borate, selenite [Se(IV)], and P at medium to high pH occurred with a negative surface and reaction at low pH occurred with a positive surface. Thus, all three species reacted with a variable-charge surface.

BEHAVIOR OF SOME IONS

Before considering the ions in detail, note that selenate [Se(VI)], sulfate, P, Se(IV), and arsenate all form bidentate, inner-sphere complexes with the surface. That is, two of the oxygen atoms provide direct chemical links to the surface atoms. When a reactant forms a bidentate link to the surface, it is appropriate to refer to the divalent ion in solution.^[1] Similarly, in the case of a monodentate link, as with borate, it is appropriate to refer to the monovalent ion.

Boric acid is fairly weak, with pH of about 9. Therefore, in the normal range of soil pH, the proportion of monovalent borate ion increases 10-fold for each unit increase in pH. The effects of pH on the charge and potential and the effects on acid dissociation therefore oppose each other: the increasingly negative electric potential favors decreased desorption; the increasing dissociation favors increased adsorption. Because the ion is monovalent, the effects of surface charge are not quite large enough to exceed the effects of the increasing value of the dissociation term. Thus, sorption increases with increasing pH.

Selenious acid is a diprotic acid with pK_1 at 2.7 and pK_2 at 8.5 in very dilute solution. The main species present in the range of soil pH values are $HSeO_3^-$ and SeO_3^{2-} , with the divalent ion increasing with increasing pH. However, because the relevant ion is divalent, the effects of the increasingly negative charge exceed the effects of increasing dissociation, and sorption therefore decreases with increasing pH.

Phosphoric acid is a triprotic acid, but the third dissociation (pH_3) is well beyond the range of soil pH. The species present in soil solutions are therefore $H_2PO_4^-$ and HPO_4^{2-} . The divalent ion increases 10-fold for each unit increase in pH up to just below pH_2 , which is about 7. Its behavior is similar to that of Se(IV), and the explanation is analogous.

EXPLAINING THE EFFECTS OF TIME

We have thus far ignored the effects of the reaction period. However, many reactants continue to react with soil, and also with goethite, for a very long period. This continuing reaction is of great importance in agriculture where it has a

Fig. 3 The effect of period of reaction at 25°C for Se(IV) and Zn on the relationship between solution concentration and amount of sorption. The lines were obtained by fitting the model described in the text to the data.

Source: From Barrow.^[1]

large effect on the need to reapply fertilizer to land. Consequently, sorption is better described by a surface, with time as the extra dimension, rather than by a line (Fig. 3).

Ions differ in the extent to which they continue to react, so that one can produce a sequence as follows: $P > Se(IV) > \text{fluoride} > Se(VI)$. For the anions, the greater the chemical attraction for the surface, the more marked the continuing reaction. The continuing reaction is caused by the diffusion of adsorbed ions into the absorbing particle. This is a slow process but can be accelerated by raising the temperature. Consequently, increased temperature increases sorption and/or decreases solution concentration.

DESORPTION

The more marked the continuing reaction, the more deeply buried the ion becomes. Although desorption curves do not seem to follow the same track as sorption curves, they can be fully predicted if the continuing reaction is taken into consideration.

Chernozems

Boris Boincean

Department of Sustainable Farming Systems, Selectia Research Institute of Field Crops, Balti, Republic of Moldova

Rattan Lal

Carbon Management and Sequestration Center, Ohio State University, Columbus, Ohio, U.S.A.

Abstract

Chernozems are the most fertile soils of the world. Besides having higher stocks of soil organic matter (SOM), they have a granular soil structure of the humus layer with high base saturation and a calcareous subsoil. The discrepancy between the conditions of soil formation under natural ecosystems and agroecosystems has caused several types of degradation in Chernozems: dehumidification, destructuration, compaction, accelerated soil erosion, etc. Consequently, agronomic productivity of crops has decreased. Nevertheless, Chernozems are highly resilient because of inherent physical and mineralogical properties, thickness of topsoil, and the mechanisms of self-restoration similar to that of a living organism. Permanent recycling of SOM is a determinant of soil functionality and its capacity to provide ecosystem and social services. Restructuring of modern industrial farming systems by using natural ecosystems as models of agricultural intensification can contribute to soil fertility restoration, increasing the competitiveness of agricultural producers, resilience to global warming, and stability of rural communities.

INTRODUCTION

Chernozems occupy 240 million hectare (Mha) in the steppes of Eurasia and North and South America. They are the most fertile soils of the world.

Chernozems are formed under steppe vegetation. Under natural ecosystems, the amounts of energy and nutrients removed from the soil are equivalent to the amount returned to the soil, creating a dynamic equilibrium and closed cycling of energy and nutrients. Plowing of Chernozems, along with replacement of perennial by annual vegetation, has drastically changed the turnover of soil organic matter (SOM). Because the input of energy with crop residues and manure is significantly lower than the amount of energy harvested with the aboveground biomass and that in uncompensated mineralization losses of SOM, the system has a strong negative energy budget and is not sustainable. Dehumidification of Chernozems has many other negative consequences on soil quality—destructuration, compaction, soil erosion, droughts, etc. Degraded Chernozems can't provide good ecosystem and social services, and their productivity is in a continuous decline.

Soil productivity is determined by its functionality. The latter depends on soil biodiversity of the whole trophic chain. The ratio between fresh organic matter (raw organic matter) and the effective and stable humus changes the physical, chemical, and biological functions of SOM. Regular additions and adequate amount of the fresh organic

matter of good quality to compensate loss by annual mineralization of SOM are essential strategies for creation of healthy and climate-resilient soils.

Agriculture requires, more than ever before, the ecological and biological restructuring of farming systems. Technological modernization of agriculture, without taking into consideration of soil as a living organism, cannot lead to a sustainable agriculture. Under these conditions, soil fertility is depleted more rapidly than it can be restored. Soils are also a non-renewable natural resource on the human time scale. Thus, agricultural intensification should be based on new agroecological principles for sustainable soil and farm management.

CHERNOZEMS

Chernozems are rich in SOM. The depth of humus layer ranges from 30 to 160 cm, and the stocks of SOM from 200 up to 650–700 Mg/ha. Thus, Chernozems are very fertile soils.

Chernozems can be grouped according to the following criteria:

- a. Depth of humus layer:
 - Shallow: <40 cm
 - Medium: 40–80 cm
 - Deep: 80–120 cm

b. Humus concentration:

- Low: <6%
- Medium: 6–9%
- High: >9%

Several theories have been proposed regarding the genesis of Chernozems: marine, marshy, and terrestrial. It was at the end of the 19th century when the famous Russian scientist V. V. Docucaeav published the book *Russian Chernozem*.^[1] He documented that the formation of Chernozem is a result of decomposition of steppe grasses, but not of forest vegetation, by a close interaction between climate, duration of soil formation, vegetation, and relief of the place and parental material. Chernozems are developed under the influence of meadow grasses and associated steppes.

Agriculture, in order to be productive and sustainable, must take into consideration all these factors and account for soil biological diversity, functionality, and productivity.

The hydrothermal conditions in the Chernozem regions are favorable to the decomposition of crop residues with the formation of humic substances. The most favorable conditions for Chernozem formation are observed in the forest-steppe region (podzolized, leached, and typical Chernozems), with more abundant vegetation, better drainage, and higher rates of humidification. Under the steppe conditions, both drainage and abundance of vegetation are not so favorable as in the previous zone. Further, the root system doesn't penetrate deep into the solum, and rates of humidification are low (calcareous, common, southern Chernozems).

Besides high stocks of SOM, Chernozems also have a granular structure of the humus layer with high base saturation and a calcareous subsoil. One of the predominant characteristics of Chernozems is the formation of organo-mineral constituents rich in nitrogen (N), phosphorus (P), sulfur, calcium, and other elements, including humate of calcium.

Chernozems occupy 240 million hectare (Mha) in the steppes of Eurasia and North and South America. Eurasia includes some western and south eastern countries of Europe up to Mongolia and China. The North American region includes prairies of Midwestern United States and southern provinces of Canada. South American continent includes regions in the southern parts of Argentina and pre-mountainous southern parts of Chile.

The Chernozem family includes different subtypes of Chernozems. In more humid regions, Chernozem grade into dark gray forest soils or Phaeozem in the World Reference Base. These soils lack the calcareous subsoil. Phaeozem occupy ~190 Mha in the forest steppes in Europe, Northern China, the prairies of North America, and pampas of South America.

A Chernozem profile is characterized by a dark humus A horizon. Virgin Chernozems (unplowed) under steppe vegetation have the A0 horizon derived from steppe grass residues. Some Chernozems also have combined humus

A + B1 horizon, where A is the most humidified horizon (the black earth topsoil) and B1 is the lower part of the humus layer (transition horizon). The other B2 horizon can exist as a separate horizon, with residual humic substances. Beneath the humus layer, there lies a calcareous horizon, which leads into the transition to parental material (C horizon).

The modern concepts regarding genesis of Chernozem are based on specific characteristics of biological turnover of energy and nutrients under steppe vegetation. Plowing of Chernozem can strongly alter the conditions of soil formation, which are discussed below in the entry.

COMPOSITION AND PROPERTIES OF CHERNOZEMS

Among inherent characteristics of Chernozems derived from the parent material include the particle size distribution or texture. It provides the physical framework and largely determines the soil's capacity to supply water and nutrients and to develop soil structure and its resistance to erosion. The textural triangle is commonly used to set the limits for each textural class (used by the USDA–NRCS, Soil Survey Division). In this method, the textural assessment is based on the relative proportions of clay, silt, and sand in a soil sample.

Majority of Chernozems are clay loams and heavy clay loams comprising a mixture of the finest clay particles, middle-sized silt particles, and coarse sand particles. The texture of Chernozem, the water-stable microstructure, the water-holding capacity, permeability, and resistance to erosion are important attributes of Chernozems. The most stable aggregates are formatted under grasslands in the presence of sufficient clay, fresh organic matter, and calcium carbonates.

Mineralogy of Chernozems depends on the parent material. Chernozems contain feldspar, mica, and illite, which are rich in potassium. That's why the effectiveness of potassic fertilizers on Chernozems is low. The clay mineralogy and colloidal humus of the Chernozems provide a high adsorptive capacity and buffering capacity or the ability to resist degradation processes.

The reaction of Chernozems is slightly acidic or neutral (pH 6.0–7.5). Chernozems are well drained with low salinity, but secondary salinization can result from irrigation with saline water. The dominant anions in the soil solution are bicarbonates in the upper layers and sulfates and chlorides in the sub-soil.

Chernozem also contains high SOM and total N concentrations. Accumulation of nitrates in soil profile can lead to their leaching, especially in a short period of time in the spring, when the evaporation is lower than the rainfall.

Soil is a living organism. The amount of organisms per 1 ha of virgin Chernozems consists of large biodiversity:^[2–7]

- 3 Mg of bacterium,
- 3 Mg of microscopic fungi,
- 1.5 Mg of actinomycetes,
- 100 kg of algae,
- 100 kg of protozoa,
- 500 kg of earthworms (their population can reach more than 300 Mg/ha),
- 50 kg of nematodes,
- 40 kg of arthropods,
- 40 kg of molluscs,
- 20 kg of reptiles and rodents, etc.
- Each cubic centimeter of soil contains 7–10 millions of microorganisms.

The diversity of life in the soil determines the functionality and the fertility of Chernozems. The biological aspect of soil fertility was neglected in agronomical science in favor of chemical fertilizers.

Charles Darwin in his monograph^[8] emphasized the importance of earthworms in ingesting and processing the soil, which is passing many times through the intestines of worms. Their contribution to increased soil porosity, aeration, water infiltration and drainage, water-stable aggregates, etc. is crucial to natural soil formation, especially in arable lands. Soil structure, bulk density, and porosity are relatively stable under natural vegetation but degrade under cultivation.

The texture, mineralogical, and chemical composition of soil are generally stable. The most changeable component of soil is SOM in spite of relatively low amount (3–6% by weight of cultivated soils). First and foremost, sustainable management of soil involves judicious management of SOM in cultivated soils. Synthesis and decomposition of SOM are critical to high soil fertility, including that of

Chernozems. In natural ecosystems, the amount of energy and nutrients removed from the soil are equivalent to the amount returned back to the soil that establishes a dynamic equilibrium and closed cycling of energy and nutrients. Turnover of the more easily decomposed fractions of SOM takes only a few months to a few years, but turnover of recalcitrant fractions occurs over hundreds or thousands of years. By replacing perennial vegetation by annual vegetation, there has been a drastic reversal of the natural accumulation of C and N in soils.

The analytical data obtained from a long-term field experiment with crop rotations and permanent crops at the Selectia Research Institute of Field Crops^[9] indicate a large deficit of energy in crop rotations with higher percent of row crops and permanent crops, especially with the so-called black fallow (Table 1).

A large part of biomass energy accumulated by the crops is harvested in plant/animal product from the field and lost from the system. Because the input of energy with crop residues and manure is significantly lower than that harvested in the aboveground biomass and the energy in uncompensated mineralization losses of SOM, the energy balance is strongly negative. Consequently, agriculture can't be sustainable in a system with perpetual energy deficit, just as is the case with every living organism. In several scenarios, losses of SOM by accelerated erosion exceed those by mineralization. In such situations, it is important to take into consideration the erosional losses of SOM.

In Chernozems, accelerated soil erosion and droughts are two sides of the same coin. It is a paradox that drought is one of the limiting factors in Chernozems, yet the abundance of water during seasons of torrential rains causes a significant degradation of soil. Because of the discrepancy between soil formation in natural ecosystems and soil

Table 1 The annual balance of energy in the long-term field experiments at Selectia Research Institute of Field Crops, average for 30 years (10³ Mdj/ha).^[9]

Variants			Output			Input			Balance	
			Taken up by aboveground biomass	Non-compensated deficit of SOM	Total	With crop residues	With manure	Total	Mdj/ha	Annual energy deficit (%)
Crop rotations, % of row crops	40 (with perennial leguminous crops)		99.3	10.4	109.7	64.8	1.9	66.7	-43.0	39.2
	50		95.2	12.4	107.6	50.4	0.3	50.7	-56.9	52.9
	60		116.9	11.5	128.4	60.2	3.7	63.9	-64.5	50.2
	70		112.6	11.5	124.1	63.6	2.4	66.0	-58.1	46.8
Continuous crops	Corn for grain	Unfertilized	100.4	20.0	120.4	35.8	—	35.8	-84.6	70.3
		Fertilized	141.0	16.8	157.8	51.1	4.4	55.5	-102.3	64.8
	Winter wheat	Unfertilized	57.4	20.0	77.4	21.0	—	21.0	-56.4	72.9
		Fertilized	80.3	15.2	95.5	29.4	4.4	33.8	-61.7	64.6
Black (bare) fallow	Unfertilized			32.7	32.7	0	0	0	-32.7	100
	Fertilized			26.9	26.9	0	4.4	4.4	-22.5	83.6

management in agroecosystems, Chernozems are degraded by numerous processes. In general, natural ecosystems should serve as a model for sustainable management of agroecosystems. Predominant use of the industrial model of intensification of agroecosystems by using inputs from non-renewable sources of energy and their by-products has exacerbated the degradation of Chernozems and accentuated the danger of disappearance of Chernozems over a long-term period. Thus, Chernozems may be termed endangered soils.^[10–13]

Regular and long-term addition of sufficient quantities of fresh organic matter is crucial to enhance biodiversity and soil functionality. It is important to understand that soils in natural conditions are always covered with vegetation but in agroecosystems they remain uncovered and are tilled for a longer or shorter period of time, depending on the crops.

Several researchers^[14–16,17] have documented that natural ecosystems have many other advantages relatively to agroecosystems: a more complex trophic interaction, a higher species and genetic diversity, a closer turnover of energy and nutrients, a higher stability and longer sustainability over time, etc.

Intensive farming practices widely adopted since 1970s included excessive soil tillage by moldboard plow; monoculture or narrow specialized crop rotations; indiscriminate use of synthetic fertilizers, especially of N; chemical pest, weed, and disease control; excessive irrigation by flooding; and manipulation of plant genomes with inappropriate root and shoot characteristics. All these practices have contributed to physical, chemical, and biological degradation of cultivated Chernozems. Among the widespread processes of soil degradation are destructure, dehumidification, compaction, accelerated soil erosion, etc.^[11,18]

Destructure (degradation) means deterioration of granular structure of Chernozems because of excessive and long-term soil tillage. For example, in virgin typical Chernozems of the Balti steppe, Republic of Moldova, the dominant fraction of water stable aggregates is 1–5 mm. Soil macroaggregates (>10 mm) and microaggregates (<0.25 mm) are negligible. In contrast, aggregate size distribution is just the opposite in cultivated Chernozems. For example, the data of dry sieving analyses for aggregate size distribution of experiments from Moldova indicate that 40–70% of soil aggregates are >10 mm in the range of clods. Furthermore, the layers beneath the plow layer (25–35 cm) are highly compacted, with prismatic structural aggregates. Principal causes of structural degradation of cultivated Chernozems are the dehumidification of the cultivated layer because of intensive soil tillage with heavy machinery.

Soil destructure and compaction reduce water infiltration capacity and exacerbate losses by water erosion. Soil tillage, and especially with the moldboard plow, also increases the rate of decomposition of crop residues and

humus. Increase in soil erosion and the rate of mineralization of SOM depletes the humus and degrades soil structure and the overall quality.

Severe deterioration of physical properties of soils indicates the inefficiency of existing farming systems. These unsustainable systems are undermining the capacity of Chernozems to maintain the productive capacity for a longer period of time. Cultivation of alfalfa (*Medicago sativa*) alone cannot significantly change the degradation trends. When alfalfa is grown in mixture with grasses, it can make a difference and improve soil quality and functionality.^[20]

Dehumidification or Depletion of SOM Contents in Cultivated chernozems is a Serious Issue

In natural ecosystems, formation of new SOM and decomposition are in dynamic equilibrium. The humus content is depleted when the rate of decomposition exceeds that of its formation. It is the SOM and its quality which enhance life support processes in the soil. The value of SOM lies in its dynamic nature—a continuous cycle of synthesis and decomposition.^[9,20–22]

It is well known that the most intensive mineralization of SOM occurs during the initial period of conversion of virgin soil to agroecosystems. In the book dedicated to 100 years from the publication of “Russian Chernozem” written by V.V. Docuchaev, it was established that losses of humus for different geographical regions in Russia range from 51–71 to 150–180 Mg/ha.^[1] The annual rate of uncompensated losses of SOM is 0.5–0.9 Mg/ha. Organic matter is the source of the energy without which the plant food elements cannot be changed into a usable form. Thus, stocks of SOM have decreased for the entire soil profile over 100 years by as much as 40–50% and even more relative to the antecedent stocks. The data from some long-term field experiments indicate the trend of humus concentration of 11% at 50–60 cm depth and 8% at 140–150 cm depth.

The long-term Sanborn experiments in Missouri, U.S.A., compared the properties of soils under undisturbed virgin prairie to that of an adjoining field cultivated to corn, wheat, and oats for 60 years without the addition of fertilizers. The cultivated field was not affected by accelerated soil erosion. The losses of SOM on cultivated fields were as much as 38%. Consequently, the granular structure of soil was degraded, it was highly compacted, its capacity to provide crops with nutrients was curtailed, and the agronomic yield was severely reduced.

Similarly, long-term field experiments conducted with different crop rotations, monoculture, irrigation, and different systems of irrigation and fertilization on typical Chernozems from Balti steppe, in the Northern part of the Republic of Moldova, have shown the adverse impacts of each of these factors alone on the SOM stocks in the upper layers and in the whole soil profile.^[10,13] The positive

impacts of the abovementioned factors of agricultural intensification on crop yields are not equivalent to their influence on soil fertility. Organo-minerals and organic systems of fertilization in crop rotation with 50% of row crop reduce the stocks of SOM to a lesser extent relative to the use of chemical fertilizers. The period of heavy loss of SOM is followed by stabilization of the losses by mineralization when the losses are lower than those in the initial period. Reduction in the concentration of SOM and total N contributes to the stabilization and even decline in crop productivity. Similar trends have been observed in many long-term field experiments all over the world and in productivity of majority of crops.^[10,23–25]

The equilibrium in the SOM concentration is determined by the climate of the region and by the farm (field) management practices. In the northern latitudes, with more precipitations and lower temperatures, ecological factors of SOM restoration are favorable than those in the southern regions.

No single factor of intensification used alone can compensate the annual losses of SOM from arable land. Integration of crop rotation with perennial legumes and grasses, use of farmyard manure, and conversion of plowing to conservation agriculture can maintain crop productivity and improve soil fertility. A judicious combination of the moldboard plowing and conservation tillage can be efficient in crop rotation with perennial legumes and grasses along with sufficient application of farmyard manure or other supplementary sources of organic amendments.^[13,17]

General awareness about these facts must be enhanced globally regarding the rapid rate of SOM depletion and to emphasize the need for SOM restoration. Predominant farming system in each country must be designed to at least maintain if not increase the stocks of SOM. Implementation of this strategy at the national level will determine the sustainability of land use together with different ecosystem services provisioned by agriculture for each society.

Water and wind erosion are the principal determinants of soil degradation and SOM depletion. Soil degradation can be reversed by mitigating soil erosion. When soil is effectively covered by vegetation, crop, or crop residues, it has lower risks of soil erosion and degradation.

Improvement in structure decreases soil losses, because of high water infiltration even on steep slope gradients. Reducing the intensity and frequency of moldboard plowing is crucial to the reduction of soil erosion. Simultaneously, the proportion of area under sod/cover crops should be increased especially in regions with torrential rains and hilly terrain. The higher is the degree of soil erosion, the lower is the level of productivity. Agronomic productivity of principal crops can be reduced by 20–30% on less eroded soils, 40–60% on moderately eroded, and 60–80% on strongly eroded soils.^[9,21,12,26] In severely eroded soils, even the B2 horizon is washed away. The degree of erosion on cultivated soils in Moldova is evaluated [Table 2](#).

The ecological functions of soils (thermodynamical, hydrological, geological, biogeochemical, agropedological, etc.) are strongly determined by the SOM concentration. The energy content of humus in Chernozems of the steppe regions is 8–9 times higher than that of crop and vegetation.^[28] The primary energy potential of Chernozems is located in the root zone.

Soils are the most important link in turnover of water and in carbon sequestration. The biodiversity of soils flora and fauna is significantly richer than that of the terrestrial biomes. However, the knowledge about the soil biodiversity and its functions is rather sketchy even with the modern science. Properly managed soils also have a high capacity to recycle nutrients. The ratio of diphosphorus pentoxide in 0–20 cm to that in 50–100 cm soil layers is >1.0, which implies that crops have the ability to “pump” P from deeper soil into the surface layers. Similar trends are observed for some trace elements.

Chernozems are highly resilient—because of the inherent physical and mineralogical properties, thickness of topsoil, and the mechanisms of self-restoration similar to that of a living organism. Soil maintains its life-support processes by continuous recycling of SOM. Thus, farming systems and management practices must be specifically designed to enhance recycling of SOM for achieving sustainability. Ecological principles must be strictly observed for achieving a more sustainable development of agriculture. Therefore, restructuring of modern farming systems of Chernozems must be realized by following the holistic

Table 2 The effects of severity of soil erosion on agronomic productivity.^[18]

The degree of erosion	The degree of losses for genetic horizons	The most probable content of humus relatively to undegraded soil, in % for soil layers		The distribution of carbonates in soil profile
		0–20 cm	0–100 cm	
Low	Less than ½ of A	75–80	65–70	At the depth of 30–50 cm in the northern part
Average	More than ½ of A or the whole A horizon	65	45–55	From the surface, very seldom at the simple deeper in the northern part
Strong	Partly or the whole horizon B1	50	35–45	From the surface

(systemic) vision rather than a reductionist (simplistic) approach. The holistic vision may include the followings:

- using landscape approach to land organization with differentiation of land use according the ecological characteristics of soils and crops;
- adopting crop rotations with the mixture of perennial leguminous crops and grasses, with a higher diversity rather than a narrow range of crops;
- reducing or avoiding the inversion system of soil tillage while retaining more residues on soil surface, more mixed crops, and cover crops;
- integrating crops and animal husbandries; and
- promoting cooperation on horizontal and vertical levels among farmers, farmers and processing industry, between all links within the whole food chain to ensure equitability between all of them.

Achieving sustainability of the entire food chain, from production to consumption and return, is essential in maintaining soil quality, minimizing risks of degradation of soil and other natural resources, and contributing to rebuilding rural communities and renewing society.

Abstract

Chloride ion is abundant in nature. Plants need it as a micronutrient. Its deficiency in plants is observed in rainy inland regions. Chloride salinity is widespread all over the world in irrigated areas. Plant species and cultivars vary in their sensitivity to excess Cl^- in the soil solution. The transport of Cl from the soil to the plant and its transport inside plant cells involve chloride channels and energy investment. It accumulates in leaves and to a lesser extent in fruits and seeds. There is a competition in the uptake and accumulation between nitrate and chloride, the two anions that are taken in large quantities by plants. Continuous presence of nitrate in the soil solution near the roots reduces chloride uptake by a factor of 2–6, enabling sensitive plants to overcome Cl salinity. The main reasons for excessive Cl in soils are excess evaporation from irrigated lands, sea inundations, and use of saline water for irrigation.

INTRODUCTION

Chlorine is found in nature in the form of negatively charged (Cl^-), highly water-soluble anion. Most of the world's Cl^- is found either in oceans or in salt deposits left by evaporation of old inland seas, which are found in deep quarries. Field and glasshouse studies in the mid-1800s to the early 1900s have shown that the influence of Cl^- on plant growth varies with the plant variety.^[1] Lipman^[2] demonstrated the beneficial effect of Cl^- on buckwheat (*Triticum aestivum* L.) growth. Arnon and Whatley^[3] suggested that Cl^- is an essential cofactor in the O_2 evolution during photosynthesis. The first complete definition of Cl^- , as a plant essential micronutrient, was described by Broyer et al.^[4]

The function of Cl^- in crop yield has been largely neglected,^[5] as it becomes a limiting factor for plant growth only in areas of high precipitation far from the sea. The negative effects of high Cl^- concentrations in soil and irrigation water on crop production are observed in coastal, arid, and semiarid areas, where freshwater sources are often scarce and the available groundwater is saline. The dependence of modern agriculture on irrigation and fertilization causes more concern on excess of Cl^- rather than on its deficiency.^[6]

CHLORIDE IN SOIL

The concentrations of Cl^- in natural sources are listed in Table 1. The Cl^- content in the soil is not an intrinsic

property of the soil but rather a result of soil management, rainfall and evaporation, and irrigation and fertilization.

The Cl^- concentration in rainwater close to seashore ranges from about 20 to 50 g/m^3 and 2 to 6 g/m^3 in inner continental areas.^[5,7] The annual amount of Cl^- deposition on land ranges from 17 to 175 kg/ha. Midcontinental areas such as the Great Plains of North America receive <1.0 kg Cl^- /ha annually through precipitation.^[5]

The chloride anion is not sorbed on soil particles at neutral and basic pH values, and therefore is easily leached. However, in acid soils containing variable-charge clays, a slight specific sorption of Cl^- is involved.^[9]

Plants can take up substantial amounts of Cl^- when soil Cl^- levels are high. At peak accumulation, the Cl^- content of spring wheat (*T. aestivum* L.) was 18 and 61 kg/ha on sites testing low and high in Cl^- , respectively.^[5]

PLANT YIELD AND QUALITY RESPONSES TO CHLORIDE

The small amount of Cl^- in precipitation, combined with the limited use of potassium chloride (KCl) fertilizer in some potassium (K)-rich inland soils, results in low levels of Cl^- in soil testing.^[5] Substantial positive responses to Cl^- -containing fertilizers have been reported for different crops in many parts of the world:^[5,6,10] barley (*Hordeum vulgare* L.), coconut (*Cocos nucifera* L.), kiwifruit (*Actinidia deliciosa* L.), oil palm (*Elaeis guineensis* Jacq.), potato (*Solanum tuberosum* L.), wheat (*T. aestivum* L.), tobacco

Table 1 Chloride concentrations in some natural sources.

Source	Chloride (g kg ⁻¹)

(*Nicotiana tabacum* L.), and sugar beet (*Beta vulgaris* L.). Typical symptoms of Cl⁻ deficiency include wilting of leaves, curling of leaflets, bronzing and chlorosis, and severe inhibition of root growth. The so-called “Cl⁻ deficient leaf spot syndrome,” the leaf spots and tissue necrosis in wheat, is caused by inadequate Cl⁻ nutrition (about 1 g/kg DM) rather than pathogen infection.^[10] The concentration range of Cl⁻ deficiency in plants varies between 0.13 and 5.7 g/kg (Table 2). Wheat yield benefits from Cl⁻ were attributed to either partial suppression of root or foliar diseases or to the enhancement of host tolerance to the “disease.”

Sensitivity to high Cl⁻ concentrations varies widely between plant species and cultivars. Generally, many woody plant species and legumes are susceptible to Cl⁻ toxicity, whereas most non-woody crops tolerate excessive Cl⁻.^[30] The critical toxicity concentration of Cl⁻ (CTCC) in saturated soil extracts varies from 10 to 15 mM for sensitive crops like common bean (*Phaseolus vulgaris* L.), grape (*Vitis vinifera* L. ssp. *Vinifera*), lettuce (*Lactuca sativa* L.), potato, and strawberry (*Fragaria vesca*) and to 70–80 mM for crops, such as barley, cotton (*Gossypium hirsutum* L.), sorghum (*Sorghum bicolor* L.), and sugar beet.^[6,30] The CTCC in plant is about 4–7 g/kg and 15–50 g/kg for Cl-sensitive and Cl-tolerant plant species, respectively (Table 2). It seems likely that factors associated with vigorous growth or Cl⁻ compartmentation within the cell could offset the inhibitory effects of Cl⁻ accumulation. The tolerance of a crop to Cl⁻ varies with the growth stage as well as climatic conditions.

The specific influences of Cl⁻ on the quality of agricultural products are not clear. Chloride generally accumulates in the vegetative parts, mainly in the leaves, while its content in grains, fruits, and seeds is very low and is hardly affected by the Cl⁻ concentration in the soil.^[5,6] Therefore, the quality of leafy vegetables is relatively sensitive to Cl⁻ such as Chinese cabbage (*Brassica rapa* L.), lettuce, and tobacco, while fruit quality is generally tolerant to high Cl⁻ levels in the soil.

PLANT CHLORIDE UPTAKE AND DISTRIBUTION

Uptake of Cl⁻ by the plant roots is an active process that requires energy. The Cl⁻ transport through the cell membrane involves the nH⁺:Cl⁻ symporter^[31] or occurs via antiport with hydroxyl ions energized by adenosine triphosphate (ATP).^[30] Specific protein channels energized by ATP for Cl⁻ transport are found both in the plasma-membrane and in the tonoplast. The fluxes of Cl⁻ in intact plants are very different from those measured in plants with excised roots. One of the schemes used to describe the control of Cl⁻ uptake and transport in plants is a homeostatic mechanism that senses vacuolar NO₃⁻ plus Cl⁻ or total anion concentration.^[32]

Chloride compartmentation appears to be highly regulated. In the chloroplast, Cl⁻ concentration remains relatively constant regardless of whether the plant growth medium is Cl⁻ deficient or excessive.^[30] Harmful effects of high leaf Cl⁻ concentrations could be avoided, if salt excluding varieties are used as rootstocks.

BIOCHEMICAL AND PHYSIOLOGICAL FUNCTIONS OF CHLORIDE IN PLANTS

Chloride has a stimulatory effect on asparagine synthetase, which uses glutamate as a substrate.^[33] The proton-pumping ATPase at the tonoplast is stimulated directly by Cl.^[34] The chlorinated indole-3-acetic acid (IAA) found in substantial amounts in some legume species seeds enhances hypocotyl elongation at 10 times the rate of IAA itself, probably because of the resistance of the former compound to degradation by peroxides.^[35] Chloride is required for the water-splitting system of photosystem II.^[3] Binding of Cl⁻ to membranes is needed for activation of the O₂-evolving enzyme. The preference for Cl⁻ over Br⁻, NO₃⁻, or I⁻ with regard to its ability to promote O₂ evolution is due to its specific ionic volume.

The ability of Cl⁻ to move rapidly across cell membranes against an electrochemical gradient and its relatively low biochemical activity are two important properties that make Cl⁻ particularly suited to serve as a key osmotic solute in plants. The accumulation of Cl⁻ by plants contributes greatly to an increase in cell hydration and turgor pressure, both of which are essential for cell elongation and stomata opening.^[16] The osmoregulatory function of Cl⁻ in

plants seems to operate at different levels.^[8] The Cl⁻ concentration range usually found in plants (50–150 mM of tissue water) exceeds its critical deficiency level by 1–2 orders of magnitudes. At low concentration of Cl⁻ (1 mM or less in the whole plant tissue), the osmoregulatory functions of Cl⁻ are presumably confined to specialized compartments in tissues or cells. These are the elongation zones of roots and shoots, the pulvini, stigmata, and guard cells, where the concentrations of Cl⁻ might be much higher than the average Cl⁻ concentration in the bulk tissue.^[6]

Activation of an H⁺ pump in the plasma membrane initiates K⁺ and Cl⁻ influx, accompanied by malate synthesis, resulting in osmotic water flow into the guard cells, and consequent stomata opening. The relative contribution of Cl⁻ and malate may vary among species and depend on the availability of external Cl⁻ and plant growth environment.^[36] In plant species such as onion (*Allium cepa* L.), which lack the functional chloroplasts for malate synthesis in the guard cells, Cl⁻ is essential for stomata functioning.^[36,37] Members of the *Palmaceae*, such as coconut and oil palm,

which might possess starch-containing chloroplasts in their guard cells, also require Cl^- for stomata function.^[13]

INTERACTION OF CHLORIDE UPTAKE WITH THE UPTAKE OF OTHER NUTRIENTS

Ammonium is taken up by plant as a cation, and therefore relatively more anions have to be taken up to maintain the electrical neutrality of the uptake process. Plants fertilized with NH_4^+ usually contain higher Cl^- levels in the tissue than plants fertilized with NO_3^- or with both N sources, irrespective of the Cl^- concentration in the nutrient solution.^[6] Thus, when Cl^- is present in the root medium, NH_4^+ uptake may increase the salt sensitivity of the plants.

The antagonism between NO_3^- and Cl^- uptake has been well demonstrated in many crops.^[6] When both Cl^- and NO_3^- anions are taken up by the root against their electrochemical gradient, Cl^- maintains its negative charge, while NO_3^- is metabolized and loses its negative charge. The accumulation of Cl^- reduces its further uptake since the Cl^- electrochemical potential gradient builds up during its accumulation in the cell.^[25] Nitrate can prevent Cl^- toxicity of avocado at a concentration of up to 16 mM in the root medium.^[25] On the other hand, Cl^- application may also be used as a strategy to decrease the NO_3^- content of leafy vegetables, as spinach (*Spinacia oleracea* L.), lettuce, and cabbage (*Brassica oleracea* L.), which are classified as NO_3^- accumulators.^[6]

Increasing concentrations of Cl^- in the root medium has generally no consistent effect on K concentrations in the plants. Potassium concentrations in the leaves of kiwifruit are significantly higher for vines receiving KCl than for vines receiving K_2SO_4 as the kiwifruit uses Cl^- rather than organic anions for charge balance, and thus maintains a high K uptake.^[11]

CHLORIDE MANAGEMENT IN IRRIGATION AND FERTILIZATION

Large amounts of Cl^- enter the field through irrigation. The amount of Cl^- added to a field with 500 mm of irrigation water containing only 200 g Cl/m^3 is only 1,000 kg/ha. This is four times more than the amount of Cl^- applied by fertilization with KCl at 500 kg/ha. The irrigation system influences the distribution of Cl^- salts in the soil. Irrigation with saline water is managed by an excess of irrigation to meet the leaching requirement for avoiding salt accumulation in the root zone.^[38] The amount of water required to wash salts out of the root zone can be estimated from the electrical conductivity (EC) of the irrigation water and the mean EC of the saturated soil extract at which no crop yield reduction occurs under sprinkler or surface irrigation.^[38]

Fertilization with potassium nitrate (KNO_3) under saline conditions might reduce the toxic effect of salinity of some woody plants even if it is associated with increased soil

osmotic potential.^[25] Under high salinity and Cl^- conditions, KNO_3 or potassium sulfate as K fertilizers are preferred due to their lower salt index and absence of Cl^- . Addition of adequate phosphorus can also be helpful in alleviating salt stress.^[6]

CONCLUSION

Chloride ion is essential for plant growth as a micro-nutrient. It is taken up by plants in large quantities when its concentration in the soil is elevated due to irrigation, fertilization, and evaporation of water from the soil surface. Cl^- deficiency was monitored in inland regions with ample rainfall. There is a wide range of Cl^- concentrations needed by plants (from Cl-sensitive plants like avocado to tolerant plants like coconuts). The main load of Cl^- is observed when irrigation with saline water is employed. The main Cl^- -rich fertilizer is KCl that is normally applied without deleterious effects.

Classification Systems

Stephen Nortcliff

Department of Soil Science, University of Reading, Reading, U.K.

Abstract

This entry briefly describes some of the general principles of soil classification including selection of the soil properties to be involved in the classification, a brief explanation of why it is necessary to classify soils, and the general principles of single or general purpose classifications. A small number of examples of general purpose classifications at international and national levels are provided along with a short discussion on the importance of soil classification as a means of communication between soil scientists and users of soil science information.

BACKGROUND

Soil varies across the earth's surface. This variation occurs both laterally and vertically and is a result of the complex interactions of the processes of soil formation in the environmental context, particularly climate, parent material, and topography. These processes have operated over varying time periods. As a consequence, some soils on the earth's surface may have been developing for thousands and possibly millions of years and are well developed and in equilibrium with their environment; others will show only the initial stages of soil development and may be only a few years or tens of years old. Often the characteristics of this latter group of soils are very strongly influenced by the nature of the relatively unaltered parent material.

An important feature of the soil is that it is not static, rather it is a dynamic natural body interacting in a complex manner with its environment. As a consequence, the soil changes through time and in space, as a response to environmental changes. As a result of this, the soil will show variation at different times within the development of a landscape. But that the soil will vary from place to place at any given time is of considerably greater importance. Taking this argument to its extreme conclusion, we might consider that no two places on the earth's surface have identical soils! Rather than accepting this extreme scenario, it is generally agreed that it is possible to group soils together into classes, within which many properties of the soil may be expected to be similar. Soil classification seeks to group these soils into soil classes or taxonomic units, and the related practice of soil survey seeks to map the soils into spatially homogeneous groups so that they may be portrayed on maps. Before a map can be produced; however, the soil surveyor needs, at the minimum, a basic soil classification system. Frequently, the soil surveyor producing soil maps will endeavor to produce soil-mapping units that correspond to the taxonomic units of the soil classification.

Soil classification is not new. In the 12th century, Yahya Ibn Mohammed, writing in his compendium entitled *The Book of Agriculture*^[1] noted that “the first step in agriculture is recognizing the soil and knowing how to differentiate between the good and the poor one.” It is interesting that there is very little documented consideration of soil classification from this time until the 19th century. In the second half of the 19th century, Dokuchaiev, working in Russia, highlighted the need to consider the nature and pattern of soils in the landscape and suggested the possibility of being able to group soils into distinct classes based on their properties and environmental context.^[2] From this time, throughout the 20th century and through the 21st century, there have been numerous attempts to classify soils, some in the context of a local landscape of a few kilometers, others on a global scale.

WHICH PROPERTIES SHOULD BE CHOSEN FOR CLASSIFICATION?

It is unclear whether the approach to soil classification in the 12th century involved only the top few centimeters or greater thicknesses of soil material, but many of the early documented classification focused on the upper soil layers, with little attention being given to underlying layers. As the knowledge concerning soils and their development have increased, so has the awareness of the need to consider the underlying layers. We identify four broad groups of these layers, from the surface downwards the O, A, B, and C, which we call soil horizons. The nature and significance of soil horizons are discussed in the entry *Diagnostic Horizons* (p. 668).

It has already been stated that part of the purpose of soil classification is to provide a degree of order to the considerable diversity of soils and soil properties found across the earth's surface. The classes are normally defined with

respect to one or a group of properties, with a particular soil having membership of the class if the values for the selected properties fall within defined ranges. The problem firstly arises in selecting the properties and secondly the ranges of properties to be used in determining class membership. In some cases, the properties selected for classification have not been properties of the soil but properties of the environment. In using environmental factors in the classification of the soils, it is assumed that there are very strong environment–soil property relationships. This was a major feature of the classification of soil by Dokuchaiev and co-workers in 19th century in Russia.

While the organization of our knowledge by means of a soil classification is a major progress toward an understanding of the nature of soils and soil distributions, there remains the often-problematical decision of choosing the right properties of soil to determine and identify the soil classes. As our knowledge of soils has increased, so has the range of properties upon which we might base a classification of soils. It is essential that there is a clear rationale for the selection of the small number of soil properties chosen often to differentiate the soil classes and to determine the class limits.

WHY CLASSIFY SOILS

The principal reason for classifying soils is to organize the vast amount of information about soils, to produce classes that have either similar properties and/or similar responses to external inputs, both natural and man-made. The production of a classification should save the investigator time and simplify the description of the soil.^[3] If many of the soils that we encounter have three or four properties in common (e.g., uniform texture down the profile, strong aggregated clay, and red color), it may be sensible to use one short name to describe them all. Having produced a framework for the classification of soils, this may provide the basis for the prediction of individual properties and behavior from knowledge of the defined class characteristics. In this respect, soil classification becomes an essential means of communication among soil scientists. It is also important in cases of identifying the most appropriate use of the soil, estimating the production, extrapolating knowledge gained at one location to other often relatively little known locations, and providing a basis for future research needs.

SINGLE OR GENERAL-PURPOSE CLASSIFICATION

One of the matters that have concerned those involved with classification of soils is whether the classification should be with respect to a single objective, a narrow range of purposes, or whether the classifier should seek to produce a general-purpose classification. The debate between those promoting either single or general-

purpose classifications has been widespread, yet the aims of these classifications are very different. Sneath^[4] argues that classification based on as many features as possible is the most “natural” classification and that such a classification will be best suited for general purposes. Certainly, a classification will have the greatest range of predictive powers, although for any specific purpose a special classification based on the features of importance to that purpose is likely to be more precise. Confusion frequently arises because the classifications have been undertaken according to the principles of general-purpose classification but then used for very narrow ranges of specific purpose situations. While the classifications may be very good at the general level, they will generally be less effective for specific needs. If the applications to specific purposes are inappropriate, they may result in erroneous predictions. The general-purpose classifications are the most widely used type of classification, both at the international and national levels. In Table 1, some of the general-purpose soil classifications are listed.

SOIL CLASSIFICATION AS A MEANS OF COMMUNICATION

Soil classification facilitates communication about soils, both among the soil scientists and between soil scientists and non-soil scientists. Because of this need for communication, it is essential that those persons using a classification are aware of the criteria used to define the classes, and the context within which these criteria were chosen. The outcomes of the classification must be understood in the context of selecting the differentiating criteria. If a soil classification is to be used as a means of communication, the principles upon which it is based and the criteria used to select the properties for class discrimination must be understood by those using it. While this is important for the communication among the soil scientists, it is of particular importance when soil scientists communicate with non-soil scientists. It is also important for the user to be aware whether there is any

perceived covariation between the properties chosen for discrimination and other soil properties, as frequently classifications based on one property or one set of properties are used by other people, although in the original specification of the classification no such covariation had been assumed. Such misuses have the potential to result in substantial misunderstanding and major errors.

In summary, therefore, the key benefits that result from soil classification may be summarized as follows:

1. Soil classifications provide a framework for soil survey and for the observations made on soils.
2. Soil classifications provide an understanding of the relationships between (selected) soil properties and the significance of these properties with respect to the usage.
3. Soil classifications provide a means of organizing research information and the communication of research results.^[11]
4. The allocation of soils to classes should provide a framework within which the laws relating to the nature and development of the soil can be discovered.^[12]
5. Soil classifications provide a means of technology transfer, where the knowledge and behavior of soils in response to different management strategies may be transferred to soils that are considered to be similar with respect to the classification.^[13,14]

CONCLUSION

It is obvious that the vast amount of information that can be gathered for each soil requires some form of organization and management. To accomplish this, some form of allocation of soils into classes is essential. To simplify the wealth of information in this manner will greatly assist the communication between groups of soil scientists and between soil scientists and others. The key to a successful classification is to identify the purpose of classification and to select criteria selected as differentiating properties that are appropriate for this purpose. Frequently, the soil classifications are misused because no account is taken of why it was devised in the first place. Using an appropriate classification can provide greater insight into soil relationships, whereas the use of inappropriate classification may result in confusion.

Classification Systems: Arab Traditional, Moroccan Case

Mohamed Sabir

Hassan Ben Jelloun

National School of Forest Engineers, Tabriquet, Morocco

Abstract

Soil science, a relatively new discipline, compared to other fields, such as botany, biology, zoology, and mineralogy, is lacking an internationally accepted taxonomic system. Traditionally, a local scientific system of soil classification was lacking in most countries of the Arab world. However, soils were mostly designated by vernacular names that stem from local agricultural practices and soil use.

BACKGROUND

Different systems of soil classification have been developed throughout the world.^[1] In the Maghreb Arab countries (Morocco, Algeria, and Tunisia), the first efforts related to soil classification were initiated in 1934 by Del Villar, who was the president of the Mediterranean subcommission of the 1st International Society of Soil Science.^[2] His principal and most important pedological studies were conducted in Morocco.

The vernacular names are used among farmers and even among agricultural scientists, and detailed soil classification system are inspirations from the ones developed in Western Europe, Canada, and the United States, especially the systems of soil classification adopted by the Commission of Pedology and Cartography of Soil of France (CPCS, 1967),^[3] FAO/UNESCO, Soils of the World (ELSEVIER/ISRIC, 1989),^[4] Soil Taxonomy (1975),^[5] and the World Reference Base (1994).^[6]

The object of this entry is to present a brief review about the soil classification scheme used in some areas of Morocco.

ANCIENT ARAB SOIL CLASSIFICATION

Knowledge about land and agricultural practices stems from before Roman times. Men in ancient times have already used many of our farming practices (manuring, liming, and crop rotations with legumes).^[7]

Most of the actual knowledge farmers used during the long period from the fall of Roman civilization to the French Revolution and for some time afterward was the local knowledge of farmers.

At the time where the people of Europe were disorganized and lived in a dark age of diseases, famine, and war for more than a thousand years, the Arabian culture flourished in the Near East, Northern Africa, and southern

Spain, where farming was reasonably good, especially under irrigation.

Some of soil classification systems and farming practices were well explained in the handbook of agriculture prepared by Ibn-al-Awam,^[7] with a Moorish scholarship, in the 12th century. Ibn-al-Awam's^[8] book of agriculture classified different land types according to their agricultural qualities as follows:

Black earth: A warm earth that gives high agricultural yields.

Red earth: A moderately warm earth with moderate agricultural yields.

Yellow earth and white earth: A cold earth that gives low agricultural yields.

Dry earth: It has two species or divisions.

Sandy earth: It has a low fertility level.

Muddy earth: It has a marly-clay texture, it is sticky and plastic, and it becomes very hard and very compact when dry.

MOROCCAN VERNACULAR SOIL NAMES

Soil classification was introduced for the first time to the Mediterranean region in 1925 through the efforts of Spanish pedologist Del Villar ([Table 1](#)).^[9] Previously, most of the soil types were designated by their color, texture, structure, degree of fertility, and water-holding capacity, despite the fact that their meaning may differ from a region to another. In the northern humid regions, soils are distinguished by their fertility. Contrariwise, in the southern arid regions, soils are distinguished by their water-holding capacity following irrigation.

Among the Maghreb West Arab countries, Morocco, Algeria, and Tunisia show climatic, geologic, and geomorphologic similarities.^[10] Therefore, some of the vernacular

Table 1 Del Villar soil classification system.

Soil types	Soil cycles	Soil sectors
1-Homocyclic type	1.1. Sialferric cycle: soil dynamics are dominated by colloidal silicon and aluminum and by ferrous sesquioxides. 1.2. Calcareous cycle: pedogenic processes related to calcareous parent rock or carbonate-rich material are dominant. Leaching of carbonate may give K horizon at depth. Distinguished soils are: soil with AC profile; soil with AKC profile (Rendzina soil, Terra-rossa soil). 1.3. Sodic cycle: pedogenic processes are dominated by sodium (Na).	S1. Oxyhumic sector: unsaturated soil with acid humus. Leaching or epigenic metabolism is strong (e.g., gley soil). S2. Siallic sector: humus is not acidic, the ratio $\text{SiO}_2/\text{Al}_2\text{O}_3 > 2$, $\text{pH} < 7$. It shows two subdivisions according to parent material and energy of epigenic metabolism: parent material: siliceous or calcareous; energy of metabolism: podzolic profile with distinct A2 horizon, podzolic profile with A2 not very distinct, Illuvial profile. S3. Siallo-ferric sector: $\text{SiO}_2/\text{Al}_2\text{O}_3 > 2$; Fe_2O_3 is high. S4. Allitic sector: $\text{SiO}_2/\text{Al}_2\text{O}_3$ is very low. Leaching is important. Podzolization is possible. Ferruginous accumulation is possible (laterite soil).
1-Heterocyclic type: pedogenic metabolism responsible for soil type is not based on known chemical process. Chemical characteristics are mixed or variable; it is the regime which is responsible of soil type individualization.		S1. Saline sector: Na is in chloride form to which other soluble salts and gypsum are added. Saline soils may be epigenic or hypogenic. Epigenic metabolism of Na (leaching) is dominant (e.g., coast marshes). Hypogenic metabolism: salts are lifted from below to the surface. Examples are: thermal sources; salty lagoons; black saline soil: gley Solontchak soil; local deposited salt sebkhas of Arab countries; saline soil with surface crust; soil with salt at depth (infraline soil); soil with low salt concentration at surface (subsoltchak soil). S2. Alkaline sector: hypogenic metabolism process is low, but endogenic process resulting from precipitation, epigenic process, and percolation is dominant (Solonetz soil).
Distinguished soils are: non-sodic-hydro-epigenic soil (alluvial soil); soil with subamphigenic or subbalanced regime (prairie soil); soil with amphigenic or		

(Continued)

Table 1 Del Villar soil classification system. (Continued)

Soil types	Soil cycles	Soil sectors
balanced regime (chernosium soil); soil with hydro-hypogenic regime (clayey–gley soil); soil with hydro-hypogenic calcification; oligogenic soil (thin A horizon); Ambrogenic or holohypogenic soil = crypto-hypogenic and pheno-hypogenic soil (soils of desert climate. Below-ground water table and lithic material are the dominant genetic factors.); mixed transitional soil types.		

soil names (Table 2) used in Morocco may, to some extent, be encountered in Algeria and Tunisi.
In Morocco (Fig. 1), several local soil names are used.

- Region I: North Western Rif Mountains.
Ferich: A thin soil formed on pelitic rock material with high percentage of flysch plates.
Rmel and ferich: Complex soil, mixture of sandy (rmel), and ferich materials.

Table 2 Vernacular soil names and their equivalent in soil taxonomy.

Vernacular soil names	Soil taxonomy equivalent names
Ferich (R1 ^a), Hajar (R1), Sgguine (R5 ^a), and Salsale (R5), Azegzou (R7 ^a)	Entisols
Rmel (R3 ^a and R5)	Psaments (Entisols)
Rmel (R1), Abiad (R1), Amlil (R1), and Sahl (R1)	Udepts (Inceptisols)
Rmel jayef (R1)	Mixed Entisol–Udepts
Biad (R2 ^a) and El Hrach (R5)	Xerocrepts (Inceptisols)
Hrach (R2 and R3)	Stony Xerocrepts
Biadi (R3)	Xerocrepts over marl
Teine (R1)	Pelluderts (Vertisols)
Tirs (R3), Tirst (R4 ^a), and Tirste (R5)	Chromoxererts (Vertisols)
Hrach (R6 ^a), Itikki or Hamri (R6), Tamakalte (R6), and Terrist (R7)	Orthids (Aridisols)
Amarigh (R7)	Salorthids (Aridisols)
Azougakh (R7) and Amerdoun mouharmel (R7)	Argids (Aridisols)
Ard Kbira (R1) and Toires (R1)	Vertic Udolls (Mollisols)
Rtab (R4) and Hamri (R5)	Xerolls (Mollisols)
Safra (R4)	Aquolls (Mollisols)
Rmel (R2 and R4), Hamri (R2, R3, and R5), and Ahamri (R4)	Xeralfs (Alfisols)

^aR1, R2, R3, R4, R5, R6, and R7 are Moroccan regions where local soil names are used.

- Abiad: White soil color (abiad means white), developed on marl and marly–flysch material.
Hajar: Non-soil with sandstone outcrops (hajar means rock outcrop and stones).
Rmel or rmel jayef: Sandy soil (rmel means sand) with red-yellowish color. This soil has low fertility, sometimes has small rock grains, and is not hard when dry.
Teine: Vertic soil with high expanding clay content and high water retention (teine means clay).
Hamri: Red soil with high content of ferric oxides.
Amlil: Lithic calcareous soil with generally white color.
Sahl: Less developed soil on alluvial sediments.
Ard kbira: Black soil with high fertility level and high agricultural productivity and is suitable for all agricultural uses with low rock content and low water infiltration rate (ard kbira means big soil).
Toiress: Brown soil with low fertility but still good crop production. Rock content of this soil is moderate. Fairly hard when dry with particular texture.
- Region II: Temara (South of Rabat on the Coast Side).
Rmel: Sandy soil with brown color. Highly permeable, not hard when dry, has low percent of stones, and may reach 2 m depth.
Hamri: Red soil with high content of ferric oxides in mixture with clay; it is weakly permeable, hard, has low percentage of stones, and may reach 1 m depth.
El hassa: Gray soil with high percentage of stones, fairly permeable, and stones may reach 0.5 m depth.
Biad: White-colored soil with low agricultural productivity and good water permeability.
Hrach: Yellow-colored soil with low agricultural productivity, good water permeability, and some stones (hrach means rough).

- Region III: Romani (South East of Rabat)
Tirs: Black to dark brown soil with high fertility, needs large quantities of water for irrigation, has good agricultural potential, contains high percentage of expanding clay and low stones, has good permeability, and is resistant to erosion.

Fig. 1 Map of Morocco, geographical situation of different regions where traditional soil names were collected (RI: North Western Rif; RII: Temara; RIII: Romani; RIV: Midelt; RV: Moulay Bou Azza; RVI: Bou Malne Daddes; RVII: Erfound).

Brach: Grayish soil that requires less water with medium agricultural potential, is slightly permeable, and has large particles and stones.

Hamri: Red soil that has particles of loam and clay diameter in mixture with stones, needs much water for irrigation with very good agricultural potential.

Biadi: White soil with dust and stone on the surface.

Rmel: Brownish soil with sandy texture, high permeability, and low water-holding capacity, no stones, and deep.

Region IV: Midelt (High Moulouya Region).

Ahamri: Red soil that has clayey texture, compact with no stones, a high water-holding capacity, gets rapidly dry and warm, and has good crop production capacity.

Tirst: This soil is black, has clayey texture, and is less or more compact with no stones. Water-holding capacity of this soil is fairly good, and it is good soil for agriculture. It shows more resistance to dryness than hamri. On slopes, when dry, may show wind erosion hazard. Parent rocks are sediments of 10 cm depth. Agricultural yields are of 1000–1200 kg/ha/yr (less than world average).

Rtab: This is dusty soil with medium texture and no stones. It is 1 m thick and holds water for 20–30 days after showers or irrigation.

Brach: Brach is dark brown compact soil with large particles and stones. It is 0.5–1 m thick and holds water for 8–10 days after showers or irrigation.

Rmel: It has silver-gray color, light-sandy texture, and low water-holding capacity.

Safra: Yellow calcareous soil (safra means yellow color) with clayey texture, hard, and shows some water stagnation, and shallow (about 15 cm thick).

Region V: Moulay Bouazza

Tirste: Black soil with slightly stony–fine texture, low permeability, high water-holding capacity, and shows little cracks when dry and good biomass production vegetation development.

Hamri: It is a red compact soil, slightly stony texture, low to moderate water permeability, and cracks when dry. This soil needs much water for irrigation and shows medium potential for agriculture.

El Hrach: This soil has reddish-gray color with stones in the surface layer, is fairly permeable, and requires low quantities of water for irrigation.

Rmel: Yellow soil of sandy texture, with no stones, and highly permeable.

Sgguine: White-colored soil with hard stony–fine texture, permeability is low, and agricultural potential is poor.

Salsale: Gray soil with low stones and has friable consistence, low permeability, and poor quality.

Region VI: Bou Malne de Daddes (arid and Saharan region).

Rmel: It has yellow soil color, fine texture with no stones, not hard when dry, fertility is medium, and water-holding capacity is very low.

Hrach: Faint red soil, very hard stony–loamy texture, fertility is moderate, water-holding capacity is low, workability is difficult, sometimes has water stagnation, and agricultural potential is medium.

Itikki or hamri: Red soil with very hard compact clayey texture, has a high water-holding capacity, its dryness is very slow, and shows a good agricultural potential.

Tamakalte: Black gray soil with a fine clayey texture, resistant to dryness, has a high water retention capacity, and has a good agricultural potential.

Region VII: Erfoud (arid and Saharan region).

Terrist: White–yellow soil, without stones, no salt, and agricultural potential is low.

Amarigh: Different colors of soil (white, yellow, red, and black) and has salinity problems.

Azegzou: Schistous non-soil and agriculture is not practicable.

Azougakh: Red soil, may have or may have not stones, and good for agriculture.

Amerdoum mouharmel: Very heavy clayey soil, dryness is very slow, and has spontaneous vegetation.

CONCLUSION

In the Maghreb Arab world, soil science, in general, and soil classification systems, in particular, have followed the same evolution as in all the circum-Mediterranean countries. In this region, agricultural practices go back to the prehistoric period, and soil names used before the development of a scientific soil classification scheme were mostly related to local agricultural practices and were based essentially on color, texture, structure, fertility, richness of stones, and water-holding capacity.

In Morocco, as likely in the other countries of the Arab world, because of the multiplicity of ethnic tribes and natural conditions (climates, geological material, and vegetation), most of these names are maybe the same to qualify different soils.

Classification Systems: Australian and New Zealand

Terry A. Isbell

Davies Laboratory, U.S. Department of Agriculture—Agricultural Research Service
(USDA-ARS), Peoria, Illinois, U.S.A.

A.E. Hewitt

Landcare Research, Christchurch, New Zealand

Abstract

This entry provides a brief review of the development of two national soil classification systems: Australian and New Zealand. Of the 15 New Zealand soil orders that are defined, at least two are virtually absent in Australian soil landscapes. Conversely, some widespread Australian soils are only partly represented in the New Zealand system. There are some soils common to both the countries that probably could be satisfactorily classified at the order level by the other system.

INTRODUCTION

Although Australia and New Zealand are relatively close neighbors both are independent island states and this probably accounts for some degree of isolation between the two countries. In terms of size, climate, geology, vegetation, and land forms, there are striking differences, and it is not surprising, that the New Zealand soil pattern is mostly very different from that of much of Australia. It also follows for these factors, and other national differences, that separate soil classification schemes have always been in use.

It is widely accepted that classification is an essential part of any scientific discipline and is a necessary part of the language of science. No classification scheme can remain static; as new knowledge is gained, soil classifications need to be updated and improved. The history of national soil classifications in Australia^[1,2] is a good example of how benefits are obtained from modifications in the light of new knowledge. This, in effect, largely explains why Australia has rightly had a succession of national classification schemes. It is also of interest to note that two of the commonly used schemes—the *Factual Key* of Northcote^[3] and the so-called *A Handbook of Australian Soils*^[4]—were a direct result of the decision to hold the Ninth International Congress of Soil Science in Adelaide, Australia, in 1968. This meeting served as a catalyst to increase rapidly the knowledge about Australian soils by means of a targeted approach to the mapping of the continent at a published scale of 1:2 million using the *Factual Key*.^[3] This was achieved on time in spite of the size and soil diversity of the Australian continent. The *Factual Key* is a bifurcating, hierarchical scheme with five categorical levels. All classes are mutually exclusive, and

the keying morphological attributes are determined in the field, including the pH and the presence of carbonate as determined by a simple field test. Most class names are descriptive, e.g., “Hard Pedal Mottled Red Duplex Soils.”

The associated *A Handbook of Australian Soils*^[4] was a separate exercise to the soil mapping project and is a compendium of morphological and laboratory data of 94 soil profiles that were visited on the 1968 Congress field excursions, plus some extra representative soils not visited in the field tours. The “Handbook” is not a formal classification but is an assemblage of “great soil groups” largely derived from Stephens.^[5] This was more or less current at the time and was essentially based on the earlier U.S. Department of Agriculture schemes that were in vogue prior to the formal advent of the early *Soil Taxonomy Approximations* of the 1960s. Both the *Factual Key* and the *Handbook* are widely used in Australia, the former mainly because of the Australia-wide map coverage at 1:2 million, while the *Handbook* is very useful because of the detailed accounts of the morphology, micromorphology, and laboratory data for a large number of widespread Australian soils. A disadvantage of the *Handbook* is the lack of a key to the soil groups. The most comprehensive of the earlier New Zealand national soil classification systems is the New Zealand Genetic Soil Classification^[6] reviewed by Hewitt^[7] in 1992. In his classification, Taylor^[6] developed what would be called soil landscape models, in which soil groups were related to environmental factors employing the zonal concepts of the Russians. The classification by Taylor was first published in 1948 as a legend to the first National Soil Map, but with time, a number of weaknesses became apparent. Examples

include the failure of the genetic scheme when applied at the scale of the farm paddock and the difficulty of soil correlation between regions. It became obvious that a new model was required that made provision for important classes of New Zealand soils.

NATIONAL SOIL CLASSIFICATION SYSTEMS IN THE MODERN ERA

In the 1970s and 1980s, there was an increase in soil surveys in some Australian states, particularly Queensland and the Northern Territory, where the then-current Northcote and Stace, et al. systems were often found to be inadequate to cater for many “new” Australian soils, particularly in the wet tropics and in the subtropics. A soil classification committee with an Australia-wide charter was set up in the early 1980s to remedy the lack of an adequate, up-to-date national soil classification. Extensive field travel was carried out in most parts of Australia to gather field and laboratory data to build up a database, which would eventually contain some 14,000 published and unpublished profiles, many with laboratory data; mainly chemical. The “First Approximation” of a new national scheme was first compiled in 1989 and was widely circulated in Australia for comment. Two further approximations were produced and circulated before the published version appeared in 1996 titled *The Australian Soil Classification* (ASC).^[2]

It should be noted that due assessment was made of the two so-called international systems, namely, *Soil Taxonomy*^[8] and the subsequent revisions of most of its orders, and the other major “international” system that of the FAO–UNESCO (1990) *Soil Map of the World* and its updated (1998) version titled *World Reference Base for Soil Resources*.^[9] While these two so-called international schemes are of considerable value and interest for comparative purposes, it is more likely that most Australian pedologists would agree on the need for an appropriate national system that is regularly updated. The possibility of using methods of numerical classification was also examined but was thought to be inappropriate because of the great variability and inconsistencies in the soil datasets, e.g., lack of representation of important groups of soils.

The Australian Soil Classification

This scheme^[2,10] is widely used in most Australian soil surveys and pedological studies, primarily in an identification role. The scheme may be described as a multicategorical, hierarchical (order, suborder, great group, subgroup, and family), general purpose scheme with classes defined on the basis of diagnostic horizons or materials and their arrangement in vertical sequence as seen in an exposed profile. The classes are mutually exclusive,

and the allocation of new or unknown individuals to the classes is by means of keys. The scheme is open-ended and new classes can be defined as knowledge increases, although these may not necessarily be added in sequence to the present list. Fourteen orders are defined (Fig. 1). An innovation is the development of an interactive key to *The Australian Soil Classification* available on CD-ROM.^[11]

The structure of the ASC has strong similarities with that of *Soil Taxonomy*, and although the emphasis is on field morphology, laboratory data have been used as appropriate. All technical terms are defined in a glossary. In a companion publication,^[10] further descriptions of diagnostic horizons and materials as well as the general occurrence of each order are given, except for Anthropeposols where data were unavailable. The major classes of each order and the use of major attributes in the subdivision of the orders are discussed. The main chemical properties used are pH and exchangeable cations, with pH commonly being determined in the field. A table is provided giving approximate correlations between ASC orders, three other Australian classifications, and *Soil Taxonomy* orders.

Perhaps the major benefit of the ASC is that it provides a means for efficient communication and a systematic framework for understanding and learning about the properties and inter-relationships of soils. Experience with the *Factual Key*^[3] suggested retention of the use of color and generalized texture profiles at high levels in the hierarchy of the new system, although formal justification of such decisions is often difficult to demonstrate. Another feature of the ASC that partly overcomes some of the problems associated with hierarchies is the use of family criteria at any level of the system.

New Zealand Soil Classification

With the advent of *Soil Taxonomy*, soil scientists of New Zealand became heavily committed to their international development, involving a 5-year testing program in New Zealand. As in Australia, difficulties became apparent, particularly with regard to its complexity. The results of the investigations showed that *Soil Taxonomy* made inadequate provision for important classes of New Zealand soils, particularly in the case of Inceptisols. Much of the new order of Andisols was based on New Zealand, where Guy Smith spent 12 months studying these and other soils. The inadequacies of *Soil Taxonomy* and the older New Zealand genetic classification to serve as an up-to-date national classification led to the development and publication of new material, largely through the efforts of Hewitt.^[7,12–15] The latest version^[13] has a helpful introductory section in which concepts, objectives, and principles are outlined. The scheme is a hierarchical one (order, group, subgroup, and series), with class distinctions based on diagnostic horizons and materials. Keys are provided to enable easy class

ALL SOILS

Fig. 1 Schematic summary of the 14 orders of the Australian soil classification.

Source: From Isbell, McDonald, et al.^[10]

Note: This figure is not to be used as a key.

definitions and identification. Total number of orders is 15: allophanic soils, anthropic soils, brown soils, gley soils, granular soils, melanic soils, organic soils, oxidic soils, pallic soils, Podzols, pumice soils, raw soils, recent soils, semiarid soils, and ultic soils. Accessory properties of the orders as well as concept, occurrence, and correlation with the earlier New Zealand Genetic Soil Classification and appropriate classes of *Soil Taxonomy* are also listed. The scheme is open-ended, and new classes can be incorporated into the hierarchy.

CONCLUSION

This brief review of the development of two national soil classification systems indicates the need for some taxa which are required for one country but not the other. Of the 15 New Zealand soil orders that have been defined, at least two (Allophanic Soils and Pumice Soils) are virtually absent in Australian soil landscapes. Conversely, some widespread Australian soils are only partly represented in

the New Zealand system. Particular examples are the widespread Australian semiarid soils characterized by profiles that feature a clear or abrupt change to a textural B horizon, which is frequently sodic. Finally, there are some soils common to both the countries that probably could be satisfactorily classified at the order level by the other system. A few such examples include arthropic soils and Arthroposols, gley soils and Hydrosols, organic soils and Organosols, oxidic soils and Ferrosols, and Podzols and Podosols.

Classification Systems: Brazilian

A.C.S. da Costa

M.R. Nanni

State University of Maringá, Maringá, Brazil

Abstract

Both technical and natural soil classification systems have been developed in Brazil for governmental and agricultural purposes, roads and building construction, erosion hazards, etc. Natural systems of classification are usually based on major intrinsic characteristics of the population being classified. Soils have their own genesis, morphology, physical, chemical, and mineralogical properties that can be used to distinguish and group them in classes with similar characteristics.

INTRODUCTION

Brazil comprises about 8.5 million km². Because of the large geographic area, diversity in climate (tropical to temperate), parent rock, and vegetation, it contains one of the largest collections of soils in the world. With the exception of the Andisols, all soil orders in the U.S. system of soil classification have been identified. The proper use of this diverse natural resource can only be accomplished if intrinsic properties are identified and used to distinguish groups of soils with similar behavior, leading to some sort of classification.

HISTORY

Soil classification systems used in Brazil, before 1947, were prepared by geologists and geomorphologists, rather than by pedologists, working in small groups without much exchange of information. The group that worked at the Agricultural Institute of Campinas probably did the earliest study on soils in Brazil. Based on this and other research, Setzer^[1] published the first soil survey of the state of São Paulo in 1949. This survey used a primitive system of soil classification that had almost no hierarchy. The class definitions were vague and difficult to use elsewhere. In this survey, soils were identified using local or regional names and grouped according to their parent rock and texture (Table 1).

The National Commission of Soils (CNS) and the Brazilian Soil Science Society (SBCS) were founded by a group of pedologists in 1947. The CNS was assigned responsibility for the inventory of soils all over the country, while the SBCS became responsible for the organization of a scientific journal, the Brazilian Journal of Soil Science, that would publish technical papers related to soil distribution, properties, and management.

After the works of Baldwin et al.^[2] and Thorp and Smith^[3] were published, the primitive soil classification system used in Brazil was abandoned and another was developed by the CNS for conducting soil surveys in the state of Rio de Janeiro^[4] and to reclassify soils in the state of São Paulo.^[5] This system employed a hierarchical arrangement, and the Great Group level was used as a reference to establish the most important taxonomic units. This was also the first time that diagnostic criteria were used to classify soils, especially diagnostic B horizons such as B latossólico and B textural, that are comparable, in part, to the Oxic and Argillic horizons of the U.S. soil classification system.^[6]

Soil classes such as Brunizém Avermelhado, Gleissolo, Solo Aluvial, Solonchak, Solonetz, Planossolo, and Podzólico Vermelho Amarelo, among others, have their origin in these entries and are identified in more than 90% of the soil maps of Brazil. Some of these classes are no longer used, but some others, such as the Latossolos, have been maintained.^[7]

The organization of soil surveys all over the country and the development of soil science groups in different research institutes and universities resulted in the definition of soil attributes necessary for the separation of soils at the Great Group level. Diagnostic characteristics included base saturation, clay activity, cation exchange capacity, sodium saturation, calcium carbonate content, and several other distinctive morphological characteristics. The criteria became more and more complex, and, with time, several new classes of soils were incorporated into the system (Table 2).

The National Soil Survey and Conservation Service (SNLCS), a federal agency that followed the National Commission of Soils, organized a Soil Classification Commission in 1978. Under the coordination of the pedologist Marcelo Nunes Camargo, a national project on the development of a revised Brazilian system of soil classification was initiated. This project resulted in the publication of

Table 1 Popular names and parent rock materials of soils in the primitive Brazilian system of soil classification.

Popular name	Parent rock material
Salmorão	Gneiss and schist
Massapé	Phyllite, micaceous schists
Terra Arenosa Branca	Sandstone
Terra Arenosa Catanduva	Sandstone
Terra Siálicosa	Sandstone and siliceous rocks
Terra Roxa de Campo	Sandstone and diabase
Terra Roxa Misturada	Diabase and sandstone
Terra Roxa Legítima	Diabase

Source: From Setzer.^[1]

three approximations in 1980, 1981, and 1988.^[7] In 1987, the SBCS also published a Special Bulletin^[8] where the Brazilian system of soil classification was summarized with the information gathered up to that time. This document was used as a standard reference for soil classification over the following decade.

From 1988 to 1995, the system suffered from neglect and a new strategy was proposed.^[9] In 1993, the SNLCS was reorganized as the National Centre for Soil Research (CNPq), one of the research centers of Empresa Brasileira de Pesquisa Agropecuária (EMBRAPA), the Brazilian federal agricultural research corporation, located in Rio de Janeiro. The new strategy involved the organization of a committee structure led by an Executive Committee, followed by a National Assistant Committee and Regional Committees. This organization permitted an active and effective participation of pedologists and other scientists interested in the development of the Brazilian System of Soil Classification. The fourth approximation, according to EMBRAPA,^[7] was based mostly on the third approximation (1988) of the system.

BRAZILIAN SYSTEM OF SOIL CLASSIFICATION

Development of a fourth approximation began in 1995. Information regarding soil profiles and classification were obtained by the Regional Committees installed throughout the country. For 2 years, the Regional Committees had several meetings under the supervision of the National Advisory Committee and the Executive Committee, which, in 1997, launched a fourth approximation during the XXVI Brazilian Soil Science Congress. At that time, the fourth approximation constituted a provisory model and was submitted to pedologists with restricted circulation for the purpose of receiving suggestions and corrections.

In 1999, after final revisions, a new Brazilian System of Soil Classification (SiBCS) was released. The SiBCS is a hierarchical, multicategorical, and open system that allows the inclusion of new soil classes.

Table 2 The introduction of new soil classes in the Brazilian system of soil classification.

Soil class	Year of definition	Explanation
Rubrozém	1956	Acid soils with humic surface horizon followed by a reddish B textural
Hidromórfico Cinzento	1958	Hydromorphic soils with a Gley and B textural horizons
Latossolo Amarelo	1959	Soils with Fe ₂ O ₃ content < 7%, brownish colors, no magnetic attraction, Ki ^a 1.5–2.2
Latossolo Bruno	1967	Soils with Fe ₂ O ₃ content > 11%, topsoil with dark brownish colors followed by reddish colors, virtually no magnetic attraction, Ki 0.2–2.2
Areias Quartzosas	1969	Soils with an AC profile derived from sandstone
Solos Litólicos	1970	Soils with AR or ACR profile
Podzólico Acinzentado	1973	Soils with a grayish B-textural horizon
Latossolo Variação Una	1977	Soils with Fe ₂ O ₃ content > 11%, dark brownish colors with no magnetic attraction, Ki 0.2–2.0
Podzólico Amarelo	1979	Soils with B textural, Fe ₂ O ₃ content < 7%, Ki < 2.2
Terra Bruna Estruturada	1979	Soils with brownish colors, Fe ₂ O ₃ > 10%, no magnetic attraction, Ki 1.70–2.10
Plintossolo	1980	Soils with Plintic horizon
Latossolo Ferrífero	1982	Soils with Fe ₂ O ₃ content > 36%, strong magnetic attraction, Ki 0.06–0.9
Podzólico Vermelho-escuro	1982	Soils with a B textural, Fe ₂ O ₃ content ≤ 15%, TiO ₂ ≤ 1.70

^aKi is the number of moles of SiO₂/number of moles of Al₂O₃, determined in the < 2 mm soil fraction after total acid dissolution.

Source: From National Center for Soil Inquiries.^[7]

This system maintains 13 classes at the first categorical (order) level, as defined in the third approximation system, and also creates a new class—NITOSSOLOS.^[7] The soil orders are presented in alphabetical order without relation to their extent in the Brazilian territory in Table 3. The other levels are designated as suborder (second level), great group (third level), and subgroup (fourth level).

Some orders include soils that previously constituted separate classes in previous classification systems (EMBRAPA).^[7] As an example, the NEOSSOLOS contain soils formerly designated as Regossolos, Solos Litólicos, Solos Aluviais, and Areais Quartzosas (Table 4).

The new system also incorporates two more categorical levels: level 5 (families) and level 6 (series), for which no

Table 3 The 14 soil orders in the Brazilian system of soil classification and the number of units at the suborder, great group, and subgroup levels.

Order	Suborder	Great group	Subgroup	Soil survey staff	FAO
Alissolos	2	5	12	Ultisols	Alisols
Argissolos	4	10	85	Ultisols/Alfisols	Acrisols
Cambissolos	3	17	69	Inceptisols	Cambisols
Chernossolos	4	10	31	Mollisols/Alfisols	Chernozems/Phaeozems
Espodossolos	2	6	27	Spodosols	Podzols
Gleissolos	4	15	53	Variable	Gleysols
Latossolos	4	22	90	Oxisols	Ferralsols

members have been defined. According to Oliveira,^[9] there is a project of CNPS to establish the classes at both levels.

NOMENCLATURE OF THE BRAZILIAN SYSTEM OF SOIL CLASSIFICATION

The names of the soil orders are formed by the association of a formative element with the termination “solo.” Table 5 presents the names of the classes, their respective formative elements, and meanings.

The edition of the SiBCS uses the definitions, horizon notations, and basic knowledge of morphological characteristics used in earlier approximations. However, in the new system, there are differences in many of the diagnostic

criteria and parameters. As an example, diagnostic attributes such as Ácrico, Álico, Epiáquico, Ebânico, Crômico, and Hipocrômico have been created.

CONCLUSION

The SiBCS, as in previous approximations, consists of an open system with possibilities for change. It is expected that this system will experience alterations in editions as the system is used and criticisms are evaluated.

Classification Systems: Canadian

Charles Tarnocai

Agriculture and Agri-Food Canada, Ottawa, Ontario, Canada

Abstract

The Canadian classification system recognizes 10 soil orders based on soil properties that reflect the dominant soil-forming processes. These soil orders are divided into great groups based on the differentiating criteria of the order to which they belong. The great groups are subdivided into subgroups based on the arrangement of the soil horizons. Finally, the subgroups are subdivided into families and the families into series. The type and degree of development of the soil horizons within the pedon, the basic soil unit, are used to determine the classification of the soil.

INTRODUCTION

Classifying soils in Canada began with the first soil survey in Ontario in 1914. This classification was based largely on geological material and texture. The first taxonomic system of soil classification was developed in 1955 and is the basis of the soil classification used. This classification has been considerably revised as additional soil information has become available, resulting in both more precise definitions to the taxa at all levels and increasing emphasis on soil properties as taxonomic criteria.

The system recognizes 10 soil orders based on soil properties that reflect the dominant soil-forming processes. These soil orders are divided into great groups based on the differentiating criteria of the order to which they belong. The great groups are subdivided into subgroups based on the arrangement of the soil horizons. Finally, the subgroups are subdivided into families and the families into series. The type and degree of development of the soil horizons within the pedon, the basic soil unit, are used to determine the classification of the soil.

BASIS OF THE SOIL CLASSIFICATION

Pedon, The Basic Soil Unit

The pedon is the basic soil unit used to classify Canadian soils.^[1] It is defined as the smallest 3-D body of soil that has lateral dimensions large enough to include representative variations in the shape and relation of soil horizons and in composition of the soil.^[2] The lateral dimension of the pedon is 1 m, if the soil horizons vary within this distance. If the soil horizons are cyclical or intermittent within a lateral distance of 2–7 m, the lateral dimension of the pedon is 1–3.5 m (half of the cycle). The vertical dimension of the pedon is the depth of the control section.

Although the pedon concept applies to the classification of all soils, it is especially relevant to soils exhibiting cyclic variation, such as Cryosols, Vertisols, and forest soils having hummocky microtopography due to blow-down of trees. Examples of pedons for these soils are given in Figs. 1–3, respectively.

Soil Horizons

Soil horizons are basic to the soil classification because the taxa are defined primarily by the kinds, degree of development, and sequence of soil horizons and layers in a

Fig. 1 Pedon of Orthic Turbic Cryosol in area of non-sorted circles.

Source: From Soil Classification Working Group.^[1]

Fig. 2 Pedon of Gleyed Vertic Black Chernozem with tonguing Ah horizon.
Source: From Soil Classification Working Group.^[1]

pedon. The major mineral soil horizons are designated A, B, and C. The major organic horizons, which are derived primarily from well to imperfectly drained upland forest vegetation at various stages of decomposition, are designated L, F, and H, and those derived mainly from poorly to very poorly drained wetland vegetation are designated O. The non-soil layers are designated R (rock) and W (water). Brief descriptions of these major horizons and layers are given in Table 1. Subdivisions of the major soil horizons are labeled by adding lowercase suffixes (e.g., Ah, Bm, and Bt). Brief descriptions of some lowercase suffixes are presented in Table 2.

CRITERIA FOR DEFINING TAXA

The criteria used to differentiate the taxa at the various levels are based on soil properties and the soil-forming processes. The criteria for the various hierarchical levels from highest to lowest are as follows:

Fig. 3 Pedon of Orthic Humo-Ferric Podzol, turbic phase, in hummocky terrain resulting from blowdown of trees.
Source: From Soil Classification Working Group.^[1]

Table 1 Descriptions of mineral and organic soil horizons and mineral layers.

Horizon or layer	Description
Mineral horizons and layers	
A	A horizon formed at or near the surface in the zone of accumulation of organic matter (Ah) or leaching of materials by solution (Ae).
B	A horizon characterized by enrichment in organic matter (Bf), sesquioxides (Bf), or clay (Bt); or by development of soil structure and/or color (Bm); or by significant amounts of sodium (Bn); or by mottling and gleying (Bg).
C	A horizon (parent material) comparatively unaffected by pedogenic processes, except for gleying (Cg) and accumulation of calcium (Cca).
R	A consolidated bedrock layer.
W	A water (hydric) layer that may occur in organic, gleysolic, and cryosolic soils. It occurs in the form of ice (Wz) in cryosolic soils.
Organic horizons	
L	A well to imperfectly drained, undecomposed horizon, composed primarily of leaves, twigs, and woody materials in which the original structure is easily recognizable.
F	A well to imperfectly drained, moderately decomposed horizon in which the original structures are difficult to recognize.
H	A well to imperfectly drained, well-decomposed horizon in which the original structure is unrecognizable.
O	A poor to very poorly drained horizon derived primarily from wetland vegetation that is subdivided on the basis of the degree of decomposition into undecomposed (Of), moderately decomposed (Om), well-decomposed (Oh), and limnic (Oco) materials.

Source: From Soil Classification Working Group.^[1]

- Order: Taxa are based on properties of the pedon that reflect the soil environment and the dominant soil-forming processes.
- Great group: Taxa are differentiated on the basis of soil properties that reflect differences in the strengths of dominant processes, or a major contribution of a process in addition to the dominant one.
- Subgroup: Taxa are differentiated on the basis of the kind and arrangement of soil horizons that indicate conformity to the central concept of the great group (e.g., Orthic).
- Family: Taxa are differentiated on the basis of characteristics of the parent material (e.g., particle size, mineralogy, calcareousness, acidity, and soil climatic factors).
- Series: Taxa are differentiated on the basis of properties of the pedon. Pedons belonging to a series have

Table 2 Descriptions of the most common lowercase suffixes for mineral and organic soil horizons.

Lowercase suffix	Description
Associated with mineral horizons	
ca	Enriched by secondary carbonate.
e	Eluviated of clay, Fe, Al, or organic matter.
f	Enriched with amorphous material, mainly Al and Fe.
g	With gray color (gleyed), mottling, and reduced conditions.
h	Enriched with organic matter.
m	Slightly altered by hydrolysis and/or oxidation to produce a change in color and/or structure.
n	With high Na content and columnar or prismatic structure.
p	Affected by human activity (e.g., cultivation or logging).
t	Enriched with silicate clay.
v	Affected by vertic turbation because of shrinking and swelling clay.
y	Affected by cryoturbation.
z	Affected by permafrost (perennially frozen).
Associated with organic horizons	
f	Consisting of undecomposed organic material (rubbed fiber content >40%).
m	Consisting of moderately decomposed organic material (rubbed fiber content 10–40%).
h	Consisting of well-decomposed organic material (rubbed fiber content <10%).
co	Consisting of coprogenous earth deposited by aquatic organisms.

Source: From Soil Classification Working Group.^[1]

similar kinds and arrangements of soil horizons whose color, texture, structure, consistence, thickness, reaction, and composition fall within a narrow range.

OUTLINE OF THE CANADIAN SYSTEM OF SOIL CLASSIFICATION

Brief descriptions of the 10 soil orders, representing the highest level of the Canadian system of soil classification,^[1] are presented in [Table 3](#), and detailed descriptions are given by Soil Classification Working Group^[1] and examples are shown in [Figs. 4–11](#).

In mineral soils, the central concept of the great group is represented by the Orthic subgroup. The other subgroups within the great group are named according to the kind and arrangement of soil horizons (e.g., Eluviated—presence of an Ae horizon), intergradation

Table 3 Brief descriptions of the soil orders of the Canadian system of soil classification.

Order	Description
Brunisolic	Soils with a Bm horizon, indicating weak to moderate soil development. They occur in a wide range of climatic and vegetation conditions including forest, shrub, grassland, and alpine.
Chernozemic	Soils with an Ah horizon >10 cm thick, color value darker than 5.5 dry and 3.5 moist, chroma <3.5 moist, and >80% base saturation where Ca is the dominant cation. They are restricted to soils with mean annual soil temperatures of 0°C or higher and soil moisture regimes dryer than humid. They are associated with grassland vegetation.
Cryosolic	Soils formed on either mineral or organic materials that have permafrost within 1 m of the surface, or within 2 m if the pedon is strongly cryoturbated. They occur in Boreal and Arctic regions.
Gleysolic	Soils with gleyed horizons and horizons with mottles, indicating the influence of periodic or sustained reducing conditions. They are associated with meadow and wetland vegetation.
Luvisolic	Soils with light-colored eluvial (Ae) horizons and B horizons in which clay has accumulated (Bt). They are associated with forest vegetation.
Organic	Soils that contain >17% organic carbon by weight and have developed on organic materials associated with peatlands or on deep upland humus (folic) of forest origin.
Podzolic	Soils with a B horizon in which the dominant accumulation product is composed mainly of humified organic material combined with Al and Fe. They develop mainly on coarse- to medium-textured acid parent materials, under forest or heath vegetation in cool to very cold, humid to perhumid climates.
Regosolic	Weakly developed soils that, thus, have only thin B horizons, if present. They occur under a wide range of vegetation and climates.
Solonetzic	Soils that have developed on saline materials and have Bn horizons that are very hard when dry and swell to a sticky mass when wet. They are associated with saline-tolerant vegetation.
Vertisolic	Soils that have vertic Bv horizons and occur in heavy-textured materials (=60% clay) that have shrink–swell characteristics. They are associated with grasslands.

toward soils of another order (e.g., Gleyed and Brunisolic), or additional special features (e.g., Turbic—presence of a Bmy horizon and Vertic—presence of Bv or Bvg horizons).

Source: Photo by Charles Tarnocai.

In organic soils, the subgroups are defined by the depth to the mineral contact (typic and terric), the degree of decomposition of the organic materials (e.g., fibric, mesic, and humic, except for Folisols, which are hemic, humic, and Histic), or special features (e.g., hydric and lignic). Detailed descriptions of the subgroups are given by Soil Classification Working Group.^[1]

CORRELATION WITH OTHER SOIL CLASSIFICATION SYSTEMS

The approximate equivalents of the Canadian taxa to those of the American system^[3] and the WRB, an international system,^[4] are given in by Soil Classification Working Group (p. 155).^[1]

The closest equivalent Canadian and American taxa are the organic soils (Canada) and Histosols (U.S.A.) and

Fig. 11 Vertisol developed on clay soils in southern Saskatchewan. Note the slickenside at a depth of ~40 cm.

Source: Photo by Charles Tarnocai.

the cryosolic soils (Canada) and Gelisols (U.S.A.). The Canadian great groups and American suborders of these two orders are nearly equivalent. For the remaining orders, however, differences in taxa are greater. For example, most of the chernozemic soils (Canada) are Mollisols (U.S.A.), but some are Aridisols, Gleysols, or Solonetz (U.S.A.).

There is a great deal of similarity between the Canadian and WRB taxa at the highest level. The closest equivalents are for the Solonetzic, Luvisolic, Podzolic, Regosolic, Gleysolic, and Vertisolic orders (Canada). The corresponding equivalents in the WRB are the Solonetz, Luvisol, Podzol, Regosol, Gleysol, and Vertisol major soil units. At the lower levels, however, differences between the two systems are greater.

CONCLUSION

The Canadian system of soil classification,^[1] which was published in 1998, is based on a system that was established in 1955. This hierarchical system consists of five categories, or levels—order, great group, subgroup, family, and series—with the classification of soils at all levels being based on soil properties. As more soil information becomes available, *The Canadian System of Soil Classification*^[1] is revised to give more precise definitions to the taxa at all levels, with new orders being added as necessary.

With the development of continental and multicontinental databases, it is increasingly necessary to harmonize the soil classifications used by various countries into a more uniform, usable form. In addition, as new soil information becomes available both nationally and internationally, the various classification systems, including the Canadian system, need to be continually updated to ensure they meet the needs of the time and reflect the state of the scientific knowledge.

Classification Systems: Chinese

Zi-Tong Gong

Institute of Soil Science, Chinese Academy of Sciences, Nanjing, China

Abstract

Chinese Soil Taxonomy (CST) is the taxonomic soil classification of China after a long history of related research from ancient to modern times and peculiarized with several main points concerning *Anthrosols*, *Aridosols*, *Ferrosols*, *Alpine Region soils*, their nomenclature, and mapping. CST can be correlated to worldwide popular systems like *Soil Taxonomy* and World Reference Base.

HISTORY

Soil Classification in Ancient China

China is one of the most ancient civilizations in the world with a long history of agricultural activities. In about 2500 B.P., the earliest soil classification in China appeared in two books, *Yugong* and *Guanzi Diyuan pian*.^[1]

Soil Classification in Modern China

It can be subdivided into the following three main stages: 1) In the 1930s, the concept of soil great groups was adopted and more than 2000 soil series were established by combining C.F. Marbut's system with Chinese practice; 2) in 1954, a Chinese soil classification was formed by following the Russian system that was further developed throughout the first National General Soil Survey (1958–1961), modified in 1978 and then accepted widely as the official system used in the Second Soil Survey (1979–1994); 3) with the increasing international exchanges, Soil Taxonomy (ST) and Food and Agriculture Organization of the United Nations–United Nations Educational, Scientific and Cultural Organization Soil Map Legend were introduced into China beginning in the 1980s. A research group of 35 universities and institutions led by ISSAS step by step, worked out a soil taxonomic classification of China—Chinese Soil Taxonomy (CST).^[2]

SPECIFIC FEATURES

Diagnostic Horizons

There are 11 diagnostic surface horizons grouped as organic, humic, anthropic, and crustic epipedons. They consist of histic, mattic, mollic, umbric, ochric, siltigic, cumulic, fimic, anthrostatic, aridic epipedons, and salic crust. There are 20 diagnostic subsurface horizons, namely

albic, glossic, cambic, ferralic, lower activity caly (LAC)-ferric, plinthic, spodic, agric, hydragric, argic, salic, sulfuric, alkaline, hypersalic, gypsic, calcic, hypercalcic horizons, and special cemented pans: clay-pan, calcipan, phosphipan, and salipan.

Diagnostic Characteristics

There are diagnostic characteristics setup in CST. They are organic soil materials, lithologic characters, lithic contact, paralithic contact, anthro-silting materials, vertic features, anthroturbic layer, soil moisture regimes, gleyic features, redoxic features, soil temperature regimes, permafrost layer, frost-thawic features, n value, isohumic property, humic property, andic property, ferric property, allitic, property, phosphic property, sodic property, calcareous property, base saturation, and sulfuric materials.

Anthrosols

Based on anthropogenic horizons such as an anthrostatic epipedon and a hydragric horizon, a fimic epipedon and phos-agric horizon, and a siltigic epipedon or cumulic epipedon, Anthrosols are grouped into static Anthrosols, fimi-orthic Anthrosols, cumuli-orthic Anthrosols, and siltigi-orthic Anthrosols.^[3–5]

Aridosols

Aridosols are classified by the aridic epipedon and one or more of the following diagnostic horizons: salic, hypersalic, salipan, gypsic, hypergypsic, calcic, hypercalcic, calcipan, argic, and cambic horizon whose upper boundaries are within 100 cm of the mineral soil surface.^[6]

Ferrosols

In tropical and subtropical China, Ferrosols are based on LAC-ferric subhorizon that has lower activity, clays, and

Table 1 Correlation between CST, ST, and WRB systems.

CST ^[1]	ST ^[9]	WRB ^[10]
Histosols	Histosols	Histosols
Anthrosols	—	Anthrosols ^a

^bPartly corresponding.

rich in free iron oxides [cation exchangeable capacity (CEC₇) 16–24 cmol(+)/kg⁻¹; (free iron/total iron) = 0.4 or more] with a total area of 2 million square kilometer.

Alpine Region Soils

Tibet region is called the third polar, which is cold and dry. The soils there are classified as cryic Aridisols that have a cryic soil temperature regime, and celic Cambosols that have a cryic or colder soil temperature regime and have frost-thawic features.

Nomenclature and Mapping

Similar to ST, the principle of a segmental continuous name has been adapted in CST. The first segment includes order,

suborder, group, and subgroup. The family name provides additional information on particle size class, mineral composition, and soil temperature regime. The Series is a second segment named independently. A 1:12 M scale National Soil Map of China based upon CST is already available.

CORRELATION

CST has become gradually known to the world since being proposed by the Chinese Soil Science Society in 1996, translated into Japanese in 1997,^[7] adopted by World Reference Base (WRB) especially for the Anthrosols in 1998, and introduction in the *Handbook of Soil Science*^[8] in 1999. The correlation between CST, ST, and WRB systems is shown in Table 1.

Classification Systems: French

Jean-Paul Legros

Environment and Agronomy Department, National Institute of Agronomic Research (INRA), Montpellier, France

Abstract

This entry summarizes very briefly the evolution of the different systems used to classify the soils in France through the 20th century. It describes the French *Référentiel Pédologique* in comparison with the World Reference Base. It indicates similarities and differences and presents the comparison between both the systems.

INTRODUCTION

France is a very small country. But it was previously the head of an empire covering a part of Africa and Asia. During the International Exhibition of 1900, in Paris, Dokuchaev explained his concepts concerning pedology, attracting the interest of the French scientists on this subject. The two facts explain the interest of French scientists in soil classification.

BRIEF HISTORY

From the beginning of pedology, the French scientists used genetic classifications of soils in relation to the work of the Russian school of Dokuchaev (1846–1903) and Glinka (1867–1927). For example, Valérien Agafonoff (1863–1955), a Russian soil scientist, came to Paris fleeing his country during the revolution of 1917. He built one of the first soil maps of France with the corresponding legend (created in 1928 but published mainly in 1936 after improvements).^[1–3] Using the previous and successive works of Lagatu (1862–1942),^[4,5] Demolon (1881–1954), Kubiěna (1897–1970), Erhart (1898–1982), and several German authors, Georges Aubert (born in 1913) and Philippe Duchaufour (1912–2000) presented a first French classification in Paris, in 1956, during the Sixth International Congress of Soil Science. A second version of this system was presented in 1962 and is known as “Aubert–Duchaufour classification.” In 1960, Duchaufour published his famous *Précis de Pédologie*,^[6] which popularized his classification system to a much wider audience. Then, in 1967, the whole French scientific community collaborated and completed the system which became the “Classification of the CPCS” (*Commission de Pédologie et de Cartographie des Sols*). This document was used

for 20 years and popularized a vocabulary used in the ordinary pedological language of French scientists, e.g., *sol brun*, *ranker*, *Rendzine*, etc.

During this period, the U.S. Department of Agriculture system and the Food and Agriculture Organization Soil Legend were developed (1960 and 1981). Simultaneously, the development of computer science and statistical science demonstrated that the soils could be classified in a more objective way by searching for the mathematical similarities between taxa and objects rather than trying to enter a soil in a more or less adapted taxon of a rigid classification system. In this context, since 1986, the French community met, worked, and presented a first version of *Référentiel Pédologique* (RP) in 1992. A second version was produced by Baize and Girard,^[7] with an English translation done by Baize,^[8] and followed by Italian and Russian translations (2000). Because several French scientists were involved in the development of both the new French trials and the World Reference Base (WRB),^[9] the two systems have many similarities in both philosophy and organization, although not necessarily in the details of vocabulary. Thus, it is logical to review the RP in comparison with the WRB.

COMPARING THE RP AND THE WRB

The following are the principal points of comparison:

- The 40 diagnostic horizons of the WRB are replaced by the 73 “Horizons de Référence” of the RP.
- The 30 reference soil groups of the WRB are replaced by the 30 “Grands Groupes de Références” (major groups of references or “GER”). But these 30 categories do not match exactly because, in the French system, the tropical soils are not considered.

This last point is regretted^[10] (10), considering the large vast experience of French scientists in Africa. These 30 *Groupes* are divided into 102 “Sols de Référence.”

- The WRB “diagnostic properties,” “diagnostics materials,” “formative elements,” and “prefixes” correspond to the “qualificatifs” (qualifiers) of the RP. In the RP, all these elements are grouped in a single list of 235 terms.

The more original point of the RP is that a diagnostic horizon alone is in general not sufficient to recognize a Référence. Several diagnostic horizons are associated to identify a *solum* (profile development as A, E, B, and C including a part of the underlying rock).^[11] For this reason, the Horizons de Référence, in the RP, are defined considering strongly their relative development (A, B, C horizons, etc.). This indicates clearly that a part of the previous genetic approach remains inside the RP. Its organization is presented in Fig. 1.

Even if it is not fully completed, the RP, richer in taxa and qualifiers for a smaller part of the world, may be considered to be more precise than the WRB. It is organized in three logical levels that are not truly hierarchical. It allows the user to identify a soil as an intermediate between two taxa, e.g., a “Regosol–Cryosol.”

Table 1 presents the approximate links between WRB and RP at the level of GER, Références, and groups.

The most specific Références of the RP compared with WRB are presented in Table 2 with short explanations.

All these demonstrates that it is very easy to go from one system to the other at the level of groups and Références even if “Calcisol” is a false cognate. (Calcisol means calcareous in WRB but saturated and not calcareous in the RP.)

The situation is more complicated at the level of soil types. Many of the qualifiers seem similar, but this may not truly be the case. Table 3 shows some of the difficulties which may be encountered.

Fig. 1 Organization of the RP.

Table 1 Relationships between the WRB groups (left) and the GER or the Références of the RP (right).

WRB	RP
Histosol	Histosol
Cryosol	Cryosol
Anthrosols	Anthroposols
Leptosols	Lithosols (superficial)
	Rankosols (on acid rocks)
	Organosols (rich in organic matter)
	Rendosols (on calcareous rocks)
Vertisols	Leptismectisols (A/C or A/R profile)
	Vertisols (with B horizon)
Fluvisols	Fluviosols
	Thalassosols (estuarine/marine soils)
Solonchaks	Salisols
Gley soils	Réductisols (dominant reduction)
	Rédoxisol (dominant oxidation)
Andosols	Andosols
	Vitrosols (with glass)
Podzols	Podzosols
Plinthosols	Not already studied
Ferralsols	Not already studied
Solonetz	Sodisols
Planosols	Planosols
Chernozems	Chernosols
Kastanozem	
Phaeozem	Phaeosols
(Greyzems)	Grisols
Gypsisols	Gypsosols
Durisols	Not already studied
Calcisols	Rendosol (Rendzine)
	Rendisols (same morphology, saturated)
	Calcosols (calcareous with B)
	Dolomitosols (with MgCO ₃)
	Calcisols (noncalcareous, saturated)
	Magnesisols (with Mg ²⁺ on clay)
	Calcarisols (calcaric within 25cm)
Albeluvisols	Luvisols (for a part)
Alisols	Not already studied
Nitisols	Fersialsols (for a part)
Acrisols	Not already studied
Luvisol	Luvisol
Lixisols	Not already studied
Umbrisols	Alocrisols humiques, Rankosols
Cambisols	Brunisols
	Pelosols (rich in clay but not 2/1)
Arenosol	Arenosol
Regosol	Régosol

Table 2 Specific Références in the RP.

Alocrisols	Acidic but without <i>argic</i> horizon (i.e., different from the WRB “Acrisols”)
Colluviosols	From colluvium, i.e., on slopes, in parallel with Fluvisols
Peyrosols	From Peyre = stone in some local French languages, i.e., with important coarse fraction
Veracrisols	Sort of Acrisols rich in earth worms

Table 4 characterizes the French soils using the RP system. The data were kindly provided by the *Service d'Etude des Sols et de la Carte Pédologique de France* (Orléans).

DISCUSSION

To pass from a purely genetic classification to an international reference system, such as the WRB, was rather a long journey for the French pedological community.^[12] The construction of the RP, initiated by Denis Baize and Michel-Claude Girard, was a good way to test the possibility of this large change in the French method of thinking.

The French community of soil science fell in agreement (vote in an Administrative Council of Association Française pour l'Étude du Sol in June 2005) on the following ideas: 1) the RP system will be updated adding the tropical soils that were so precisely studied in the period of the French African Empire and 2) this new version of the RP will be built taking in consideration the WRB to get a full compatibility between the two systems. Working in such a way, French scientists will conserve their national system allowing them to focus on such taxa for regional reasons but preserving the international dialog through the WRB.

Table 4 Inventory of the French soils using the RP (from INRA-SESCPF).

RP	% of France	Corresponding WRB group
Calcosols, Brunisols	48.5	Cambisols
Luvisols	14.5	Luvisols
Rendosols	8.3	Calcisols (p.p)
Fluvisols	7.8	Fluvisols
Podzolized Luvisols	6.4	Albeluvisols
Podzols	5.6	Podzols
Lithosols	2.3	Leptosols (p.p)
Rankosols	1.8	Leptosols (p.p)
Andosols, Vitrosols	1.0	Andosols
Arénosols	0.8	Arenosols
Rédoxisols, Réductisols	0.4	Gleysols
Régosols	0.4	Regosols
Salisols	0.4	Solontchaks
Histosols	0.3	Histosols
Phaeosols	0.1	Phaeozems
Vertisols	0.1	Vertisols
Planosols	0.1	Planosols
Autres sols et surfaces	1.2	Others soils and surfaces

CONCLUSION

For the French scientific community, the development of the RP is a good opportunity to work together on the concepts of the soil classifications and to study the genesis and the functioning of the soils identified in France. Moreover, in the RP volume, the texts that present the Andosols (the soils with hydromorphic features and different kinds of humus) are valuable contributions to pedology. Nevertheless, the interest in the RP, at an international level, seems limited because of its great similarity with the WRB.

Table 3 Differences between qualifiers in WRB and RP.

Case	Problem	Examples	
		WRB terminology	RP terminology
1	Term specific of one of the two systems (scarce case)	Carbic	Clinohumic (isohumic)
2	Same meaning but different terms (scarce case)	Alumic (Al sat>50%)	Aluminic (Al ³⁺ dominant)
3	Same name but slightly different meanings (general case)	Magnesian Ca ²⁺ /Mg ²⁺ <1	Magnesian 0.2<Ca ²⁺ /Mg ²⁺ <2
4	Same name but very different meaning (scarce case)	Ruptic	Ruptic
		Vertical discontinuity	Lateral discontinuity
5	Different orthography but same meaning (scarce case)	Bathi (prefix)	Bathy
		Between 100 and 200 cm	Found at depth

Classification Systems: Historical Developments

Dan H. Yaalon

Institute of Earth Sciences, Hebrew University of Jerusalem, Jerusalem, Israel

Abstract

Although ancient farmers and agriculturists recognized the diversity and differential quality of their soils by giving them names, soil classification—except for taxation purposes—was developed only at the end of 19th century, following the Dokuchaev and followers' recognition of soil profiles as specific natural bodies. National or local soil classification systems were commonly used when mapping soil resources. Only the hierarchical six-levels of U.S. Department of Agriculture Soil Taxonomy, which promotes quantitative limits with the concept of diagnostic horizons, and the International Society of Soil Science (renamed as International Union of Soil Science), which sponsored two-tier and a less comprehensive world reference base for soil resources, can claim expanding worldwide use.

INTRODUCTION

Soil classification is an important tool in the studies of soils, enabling the establishment of order and possible relationships between pedons and polypedons at various locations. It is a major tool for the transfer of knowledge and scientific communication in the use of soils for many different purposes. Soils are one of the more complicated systems in nature, possessing both basic properties resistant to alteration and properties subject to relatively rapid, seasonal, periodic, or human-induced changes. The logic of soil classification recognizes several possibilities or ways of grouping the great variation in soil properties, from purely technical soil classification systems involving only a few selected properties, needed to be recognized for specifically designed use, e.g., salinity content when planning for irrigation, to comprehensive soil profile and its surroundings classifications, enabling the interpretation of past soil scape development and possible changes in the future.

Like modern pedology recognizing soil as an independent body derived through processes controlled by five defined soil-forming factors, soil classification is a young enterprise without deep roots in antiquity. Although attempts were made to arrange and classify soils according to these perceived genetic processes, the consensus is that basic soil classification must avail itself of recognized properties and features from the complete soil profile and chosen for their pedogenetic significance. The two books compiled by Finkl^[1] and in 2003 by Eswaran et al.^[2] contain a wealth of articles excellently illustrating the manifold approaches suggested and taken during the development of soil classification since the end of the 19th century. Other background materials will also be considered in this entry.

BEGINNING OF CLASSIFICATION

Soil classification, like all classifications, is a human construct made to organize better manifold information for a definite purpose, e.g., to prepare them for use, to simplify communication between soil users and scientists, and to establish order and relationships between soil classes. Because soils are essentially deterministic bodies, it does not entail discovery or theory but rather observations based on an established conceptual framework, which may vary as science develops. There is no natural classification. In soil science, its major use to establish and monitor soil resources at various scales, besides serving as a baseline for the study and evaluation of the nature, i.e., properties and processes, of its soils.

Ever since the modest beginnings of agriculture, some 10,000 years ago the ancient farmers recognized the differences in the productivity or value of the soils depending on their texture, color, thickness, stoniness, and other properties. The first official classification was probably established in China during the Han dynasty, listing some 30 soil types for taxation purposes. The ancient Chinese also mapped the soils and produced a written soil symbol that recognizes the difference between topsoil and subsoil. But this had little influence on the development of soil classification. In the ancient Middle East, Southern Europe, or Central and South America, though high-level agriculture flourished during the various historic civilizations, differences in soils were duly recognized and named. But the ancient and classical scholars did not deal with soils as a worthy object of study and interest.

During the Enlightenment (17th and 18th centuries), learned societies began to flourish in Western Europe, including various efforts to improve agriculture, which required the recognition and mapping of the land and soil

resources and the beginning of an orderly soil classification.^[3] The Swedish naturalist Carl Linnaeus (1707–1778), the father of binomial plant classification (*Species Plantarum*, 1753), extended this similarly to animals and minerals (*Systema Naturae*, 1758), which also included some soils. However, Carl Linnaeus's terms *argilla communis*, *arena nobilis*, and *humus ruralis*, like those of his contemporary mineralogist–chemist Johann Wallerius (1709–1785) in Uppsala—*humus rubra* or *umbra*—did not catch on. It must be remembered that for both these savants, *humus* meant topsoil, just like *vegetable mold*, later for Charles Darwin (1809–1882) in his pioneering earthworm studies (1835, 1881), was also meant as arable topsoil. An essentially agrogeological concept recognizing a few source materials for the soils or evaluating its productivity for taxation purposes prevailed in recognizing various soil types.

When new ideas about the nature and origin of soils as independent bodies in nature, derived and evolved from the interaction of external and internal factors, emerged in the second half of the 19th century by Dokuchaev (1846–1903) and Hilgard (1833–1916), this was followed rapidly by incorporating the new conceptual framework into an orderly soil classification system. Dokuchaev presented his system in 1879^[4] to be slightly modified by his student and collaborator Sibirtzev (1860–1899) and also disseminated by him^[5] through his widely used textbook of soil science.

The two ideas introduced and widely used ever since were that the unit of soil classification is the soil profile (without defining its spatial extension) and the zonal concept defining the major soil types in the zonal (normal) order from the tundra in the north to the desert steppe in the south, with intrazonal and azonal soil groups as special orders. The scheme provides a top-down hierarchy. It defined a relatively small number of soil types as the major genetic unit, essentially equivalent to plant *genus*, to be subdivided into subtypes as needed or gradually recognized. Numerous folk names for soils, like Chernozem and Podzol, were introduced, which continue to be used in various transformations. In North America, where the zonal regime from east to west is more prevalent, the pioneering pedological work of Hilgard resulted in the recognition of the mid-continental border between the eastern leached humid soils and the western acidic soils with CaCO₃, later incorporated in the influential Marbut (1863–1935) scheme of the U.S. Department of Agriculture (USDA) classification as *Pedalfers* and *Pedocals*.^[6] The new, essentially zonal genetic schemes replaced the Russian soil type term by the *Great Soil Group* category, reflecting the control of soil-forming processes over time.^[7] It became the major unit for knowledge transfer in the American and in many other countries' classification systems,^[1,2] described by modal or centrist properties. At the same time, the American soil classification continued to use the concept of *soil series*, introduced in 1903 (instead of soil type) for the principal unit of detailed mapping, for soil bodies of similar

profile morphology, and for similarity in observed and described property features.^[8] It is thus most nearly akin to the concept of *species* in the plant kingdom. They have geographical names according to places where the polypedon was first described; their number in the United States reaches tens of thousands. Related soil series are grouped into *soil families* and *subgroups*, thus providing a down-to-up hierarchy, the opposite of the Russian classification.

The idea of the climatogenetic origin of the zonal soils dominated the concepts of classification up to the middle of the 20th century, even where the zonal grouping was not as clearly evident as in Russia. Strongly weathered and well-developed soils in the tropics and subtropics also caused problems.^[2] In soil survey mapping, only natural soil properties not affected by human activity or degradation were considered, causing another problem in disregarding altered (metapedogenetic and anthropogenic) soils in all classifications. Soil classification schemes and their logic were frequently discussed,^[1,2] especially at International Soil Science Congresses, but no international consensus emerged and most countries developed their own local classification. There is no doubt that this impeded the development of pedology to some extent, especially in the ease of communication with scientists in related fields and with users of soil maps.

MODERN SOIL CLASSIFICATIONS

In the 1950s, the leaders of the USDA (Charles Kellogg, 1902–1977) decided to develop a new comprehensive soil classification and charged Smith (1902–1981) with the task. He did this over a period of 25 years, developing a completely new system with the help and cooperation of a number of American and international colleagues through a series of seven approximations and international committees, publishing it in 1975 as *Soil Taxonomy—A Basic System of Soil Classification for Making and Interpreting Soil Surveys*. It is an open-ended system subject to continuous testing and revision. A *Second Edition* has been issued in 1999. It is a six-level hierarchical system with 12 soil orders at the first level. Using a completely new nomenclature, originally subject to considerable criticism because of this, these new terms have gradually entered common use and especially the modern textbooks. Its major innovations are the consistent use of quantitative limits (rather than “modal values”) of observed properties and especially the use of diagnostic horizons (see the entry *Diagnostic Horizons*, p. 668) as the major differentiating feature at the higher levels of the hierarchy. Though originally a strictly properties classification, alleged genetic processes interpretations have gradually become incorporated.^[2]

During the last decades, the International Union of Soil Science (IUSS, previously International Society of Soil Science) sponsored an international working group and meetings to develop the world reference base for soil

resources (WRB) that would enable correlation with many national soil classification systems. The WRB system was developed essentially from the revised FAO/UNESCO World Soil Map Legend and is the second system with a claim of a more or less worldwide acceptance. (See the entry *World Reference Base for Soil Resources*, p. 2650, for more information.) It is a two-tier comprehensive system with 30 reference soil groups at the first level, also using diagnostic horizons as a differentiating feature. The second-level qualifiers include many anthropogenic properties that are one of the major differentiating features from the USDA Soil Taxonomy. It has been officially adopted by the IUSS in 1998 for general correlation with other soil classifications.

OTHER CLASSIFICATIONS

Besides the above-mentioned basic soil classifications, it should be remembered that the pedogenic reference profiles are not the only one in use. Although enabling expansive interpretations and behavior predictions, especially when related and neighboring soils are also identified, comprehensive profile examinations are time consuming and costly. For many specific use or limited information needs, a technical classification of a limited number of properties may be equally useful. Thus, several limited property surveys and selected physical determinations are used, especially in engineering classifications for construction purposes. Similarly, low- to medium-level sampling for selected analyzed elements is used in geochemical surveys. When plotted on maps, these have often provided good baselines against which more specific geochemical variations of these elements, reflecting natural or human-induced variations, can be appraised. In all these cases, the range and desirable or non-desirable limits of the examined properties must be known *a priori* or determined separately.

Other developments were various attempts to use numerical classification methods and dynamic computer simulation models to shorten the time-consuming profile analysis, including kriging geostatistics, fuzzy, and fractal analysis, for the interpretation and quantification of spatial problems in recognizing actual soil bodies in alleged soil continua and in predicting interpolative properties needed for better classification of soil landscapes. These computer-assisted methods are more applicable to soil mapping and are not likely to replace the basic need for comprehensive soil classification schemes enabling multifaceted interpretations and predictions.

CONCLUSION

Reviewing the developmental history of pedological soil classification, it becomes evident that at least two well-elaborated systems make claim for a more or less worldwide acceptance. General consensus was not reached.^[1] National or regional soil classification schemes are most likely to continue to be used,^[2] especially as the need for more and better evaluation and interpretation of soil resources becomes necessary. The problem of delimiting soil bodies and their actual 2-D and 3-D limits as the base for the classification used will probably stay with us for a long time.

Abstract

In ancient India, the agriculturists were quite conscious of the nature of soils and its relation to the production of specific crops of good economic return. Therefore, native soil classification was made on the basis of fertility, climate, and the land revenue system. This vast knowledge of the agriculturists became tradition, and the same had been passed on from generation to generation and was transformed into pastoral songs, maxims, and proverbs that acted as guidance to the farmers. Scientific interest in the characteristics of Indian soils began in 1846, and in 1898, four major groups of soils (Indo-Gangetic alluvial soils, black or *regur* soils, red soils, and laterite and lateritic soils) were recognized. Starting from 1932, various soil maps of India were prepared, and in 1954, a revised soil map of India was prepared on the scale, 1 in. = 70 mi. and it showed 20 broad soil classes. This map was revised, which provided the extent and distribution of the different soil classes and their equivalents available in the U.S. soil classification system. Based on the data of the soil resource mapping project of various states, a simplified three-level classification of soils of India can be systematized for both classification of soils and analogous transfer of agrotechnology generated at various stations to similar soils as classified and delineated in the soil map.

INTRODUCTION

Soil classification deals with the grouping of soils according to their suitability to produce plants and crops of economic importance and their use for habitation, recreation, and industry. Agriculture was the mainstay of the people in ancient India and the agriculturists then were quite conscious of the nature of soils and its relation to the production of specific crops of good economic return. According to recorded information, in ancient India, in the period 2,500 B.C. to 600 A.D., a vast knowledge acquired by the then agriculturists by experience has become tradition, and the same has been passed on from generation to generation. However, a major part of this has been forgotten and thus has become a story of the past. Experiences transformed into instructions that had been molded intelligently and ably in the form of pastoral songs, maxims, and proverbs that guided farmers for farming. In this way, the farmers were trained enough to make a choice of a particular soil for a specific crop.

SOIL FERTILITY-BASED CLASSIFICATION OF SOILS

On the basis of fertility, soils were made into two classes, *urvara* (fertile) and *anurvara* or *usara* (sterile). *Urvara mrittika* (fertile soil) was again subdivided into different kinds in view of crops such as *yava* (barley), *tila* (sesamum), *vrihi* (rice), and *mandiena* (mung). On the other hand, *anurvara mrttika* (sterile soil) was subdivided into *usara* (sand ground) and *maru* (desert). In addition, the soils that were irrigated by river and rainfed were known as *nadimatrika* and *devamatrika*, respectively.

SUITABILITY OF CROPS AND SOIL CLASSIFICATION

In the *Arthasashtra* (ca. 300 B.C.), soils were said to be classified on the basis of suitability of crops. Lands that used to be beaten by foam near the river bank were considered suitable for growing pumpkin and gourd. Lands

that were frequently flooded with water were considered suitable for long pepper, grapes, and sugarcane. Lands near wells were cultivated to vegetables and root crops. Lowlands (lakes) were used for green crops, and marginal furrows between any rows of crops were considered suitable for fragrant plants and medicinal herbs.

CLIMATE-BASED SOIL CLASSIFICATION

Caraka divided the lands into three classes, namely, *Jangala*, *Anupa*, and *Sadharana*, according to the nature of the soil and climate.^[1]

Jangala region means dry places/plants (xerophytes).

Anupa region indicates marshy or swampy and watery plants (littoral or inland). These areas are thickly overgrown with forests, bowers, and trees, and flowers encircled by verdant trees and tender creepers.

Sadharana region literally means the ordinary plants (mesophytes). These regions are endowed with creepers, plants, and trees of both classes, i.e., the *vanaspati* and *vanaspatvas*.

As suggested by Misra Chakrapani^[1] in *Visva-Vallabha*, land is described as arid, wet (i.e., marshy), and moderate (i.e., neither too dry nor too wet) and is distinguished by six tastes through color. It is described that gray-colored, pale white, black, white, red, and yellow soils are sweet, sour, salty, bitter, pungent, and astringent in taste, respectively. It also described that land that is littered with anthills, pits, and stones is saline and gravelly, has water at great depth, and is considered to be poisonous so far as planting of trees is concerned. In a region where trees and plants are blighted with frost and in a place littered with stumps, laying a garden is not advisable.

Jala-Bhumi: Krishni-Sukti, a comprehensive book on “agriculture science” attributed to Kasyapa (Misra Chakrapani^[1]), classified land into: 1) wet lands for paddy fields named as *suli bhumi*, *jala-bhumi*, and *sasya bhumi*; and 2) dry lands called *adhaka bhumi*, *tara bhumi*, and *usa bhumi*.

Land with a mild color like the sapphire or the plumage of a parrot, or is in the color of conch or the moon or is bright like molten gold, is considered as excellent.

REVENUE SYSTEM OF LAND CLASSIFICATION

In ancient India, as in modern times, land revenue was based on income from land. In other words, the revenue was rated according to the productivity and kind of soil.

Manu, the *Arthasashtra*, and the *Sukraniti* presuppose a gradation of land, survey, and measurement, calculation of outturn, as well as expenses per unit of land. It is indicated in the *Arthasashtra* and the *Smrtis* that laid stringent rules about leaving not only a good producer's surplus but also a

classification of soil on the basis of fertility. The king's share did not necessarily mean a fixed share. It was determined on the basis of soil fertility and by the needs of the state or of the cultivator. Measurement and survey and the differentiation of soils according to their productivity thus indicate that land revenue assessment was not permanent, and it used to be revised at times, although a constant revision was not felt necessary. Megasthenes, in his travel notes, recorded that Maurya officers were most likely concerned with the measurement and supervision of alluvial deposits for revenue purposes.^[2]

During the 16th century in India, the land assessment classification was based on the suitability of soils for crops.^[1] It also considered other factors such as texture and color of soils, availability of water, slope of the land, and yield of crops. Considering all these, in addition to marketing facilities for the produce, fair estimates of land values were arrived. The land that was dependent solely on rainfall was called *barani*, watered by wells was *chahi*, irrigated by canal was *nahri*, and moistened by river percolation was *sailabi*. In addition, local names of soils that conform closely to the soil classes were also developed. An example of this from Chhattisgarh indicates four classes of soils like *matasi*, *dorsa*, *kanhar*, and *bhata*. These soils are in a catenary sequence, wherein *matasi* are yellow soils on the upland or level land with loam to clay loam and loamy clay in texture and yield good paddy. *Dorsa* soils are on the slopes, darker, and with the same texture as of *matasi* and yield good paddy. *Kanhar* soils are in lowland areas, dark and slightly heavier than *matasi* and *dorsa*, and yield good paddy and wheat. *Bhata* soils are barren wastelands on uplands with gravelly sandy soils and are reddish yellow.

Red soils of Jhansi district of Uttar Pradesh are known as *parwa* and *rakar*; the former is a brownish gray soil with loam to sandy clay loam texture, whereas the latter is not useful for cultivation.

The red soils of Telangana district of Andhra Pradesh are known as *chalkas*, which are sandy loams located on highlands and are cultivated for kharif crops. In Andhra Pradesh, the pale brown to brown soils are known as *dubba* soils. These soils have low fertility and suffer severe erosion, and thus are submarginal lands and more suited for pasture and forage crops. Similarly, in Orissa state, the soils are classified as *at*, *mal*, *berna*, and *bahal* according to their topographic situation. The revenue system of soil classification and these local names provide an index of soil fertility.

Initiatives During the 19th to 21st Century

Scientific interest in the characteristics of Indian soils began when the Geological Survey of India started studying the soils and the underlying strata in 1846.^[1] In 1898, Leather recognized four major groups of soils in the country: 1) Indo-Gangetic alluvial soils; 2) black or *regur* soils; 3) red soils; and 4) laterite and lateritic soils.

Table 1 The extent and distribution of the different soil classes of India as represented in the soil maps on 1:250,000 scale along with their equivalent to U.S. Department of Agriculture, U.S. nomenclature system.

Major soils (traditional name)	Extent		Distribution in states	Soil orders U.S. soil taxonomy
	*000 ha	Percentage		
Alluvial	100,006	30.4	J&K, HP, Punjab, Haryana, Delhi, UP, Gujarat, Goa, MP, MS, AP, Karnataka, TN, Kerala, Puducherry, Bihar, Odisha, WB, ArP, Assam, Nagaland, Manipur, Mizoram, Tnpura, Meghalaya, A&N	Inceptisols, Entisols, Alfisols, Andisols
Coastal alluvial	10,049	3.1	AP, Karnataka, TN, Kerala, WB, Gujarat, Odisha, Puducherry, Lakshadweep, A&N	Andisols. Inceptisols. Entisols
Red	87,98	26.8	AP, Karnataka, Kerala, TN, Puducherry, Rajasthan, MP, MS, Gujarat, Goa, ArP, Assam, Manipur, Meghalaya, Nagaland, Mizoram, Tripura, Delhi, UP, HP, A&N	Alfisols, Ultisols, Entisols, Inceptisols, Mollisols, Andisols
Laterites	18,094	5.5	AP, Karnataka, Kerala, TN, Puducherry, MS, Odisha, WB	Alfisols, Ultisols, Inceptisols
Brown forest	540	0.2	Karnataka, Maharashtra	Mollisols. Inceptisols
Hill	2,262	0.7	Manipur, Odisha, WB, Tripura, Nagaland	Inceptisols, Entisols
Terai	326	0.1	UP, Sikkim	Mollisols, Entisols
Mountain meadow	60	—	J&K	Mollisols
Sub-montane	104	—	J&K	Alfisols
Black	54,682	16.6	MP, MS, Rajasthan, Puducherry, TN, UP, Bihar, Odisha, AP, Gujarat	Vertisols, Mollisols, Inceptisols, Entisols, Aridisols
Desert	26,283	8	Rajasthan, Gujarat, Haryana, Punjab	Aridisols, Inceptisols, Entisols
Others [†]	28,305	8.6	—	—
Total	328,700	100	—	—

[†]Includes glaciers (0.4%), sand dunes (0.01%), mangrove swamps (0.04%), salt waste (0.01%), water bodies (0.1%), rock land (0.25%) and rock outcrops (7.8%). MP, Madhya Pradesh; MS, Maharashtra; UP, Uttar Pradesh; J&K, Jammu and Kashmir; TN, Tamil Nadu; AP, Andhra Pradesh; ArP, Arunachal Pradesh; WB, West Bengal; HP, Himachal Pradesh; A&N, Andaman and Nicobar Islands.

The first soil map of India was prepared by Schokalsky in 1932.^[1] Wadia, Krishnan, and Mukherjee^[3] mentioned that soil groups were nearly coterminous with the boundaries of the geological outcrops. Vishwanath and Ukil^[4] prepared a soil map of India portraying the different climatic types on the basis of N.S. quotients by adopting color and texture as units of classification, and these were correlated with four major climatic zones (arid, semiarid, humid, and perhumid). In 1954, a revised map was prepared at Indian Agricultural Research Institute, New Delhi, on the scale 1 in. = 70 mi, and it showed 20 broad soil classes.

Integrating the effects of climate, vegetation, and topography, 16 major and 108 minor soil regions were identified and brought under 27 units by Raychaudhuri et al.^[5]

The soil map was revised by Raychaudhuri^[6] and later on by Raychaudhuri and Govindarajan.^[7] This map provided the extent and distribution of the 23 soil classes in the map and their equivalents available in the U.S. Department of Agriculture system.

Velayutham^[8] gave the idea of simplified three-level classification with the 1st level of 23 major soil groups and within each major soil group,^[5,6] the corresponding and nearest soil families (1,247 families) and series can be grouped in the next two levels, respectively. This can be

modeled for various states of India, from the data of the soil resource mapping project^[9] (1985–1996) of various states, based on key functional parameters (just as functional genomics) of soils in relation to sustainable land use and management. Such a national soil classification, which is systematic and systemic in character, can also be consistent enough to relate our (Indian) soils with other schemes of soil classification for international correlation and reference and comprehension.^[10]

Bhattacharyya et al.^[11] have given extent and distribution of 11 major soils as represented in the soil maps on 1:250,000 scale along with soil orders of the U.S. Soil Taxonomy (Table 1).

CONCLUSION

To develop a soil classification scheme, consistent research on pedology to understand soil-forming processes is necessary to link soil parameters with level/category of soil classes and scale of mapping. The U.S. Soil Taxonomy was officially adopted as a scheme of Indian soil classification, and the soil scientists engaged in soil survey and mapping used it for all research purpose.

Moreover, the soil taxonomy, being an open system, permitted revision of soil groups as and when new soils are identified in the field. However, for practical purposes, the 23 major soil groups classified and the local names of soils borne out of indigenous technical knowledge as discussed above prevail and appear useful for common understanding and extension advisory purpose.

Abstract

Numerous developing countries, with agricultural and natural resource management traditions dating back to several thousand years, have generated, via hundreds of ethnic groups living in dozens of different ecological zones, an immense collection of indigenous natural resource management and agricultural knowledge as well as ethnopedology, i.e., soil type properties developed by indigenous technical knowledge (ITK). These soil types have been the basis for the “sustainable land management” (SLM) concept. This knowledge on soil classification, unique to a given culture or society, is unfortunately largely ignored in the so-called developing world in spite of the increasing number of studies conducted by international and locally functioning establishments, such as the World Bank, International Crops Research Institute for the Semi-Arid Tropics, International Board for Soil Research and Management, the Institute of Indigenous Technology of the Iowa State University, United Nations Educational, Scientific and Cultural Organization, and United Nations Environment Programme. ITK obtained throughout the relevant world programs is concerned with a wide range of subjects from improved farm implements, to soil classification and SLM.

INDIGENOUS SOIL CLASSIFICATION AND LAND USE

Indigenous soil classification systems should be regarded as complementary information to science-based soil maps, which bear the advantage of being widely recognized and communicated between farmers, extension services, and scientists.^[1,2] The indigenous soil classification of the Mossi of Burkina Faso is a good example, for having been largely obtained by interviewers, for the relevant and widely accepted soil attributes for use in the construction of contemporary land use management activities. Moreover, Dialla's^[3] study on soil classification recognizes four major classes of soils based on texture, whereas topographical position is the major grouping parameter, with texture as a lower-order diagnostic property, in some West African indigenous soil classifications.^[4–6] Similarly, many farmers in African drought-prone areas, such as Senegal, Mauritania, Burkina Faso, and Mali, have developed distinctions between soils bound to their major limitations such as flooding frequencies,^[2] whereas Maglinao's^[7] indigenous soil classification represents an approach on a central concept (Table 1).

Maglinao's concept is concerned with depth, color, structure, and base saturation of surface and subsurface horizons like the Mossi farmers^[3] four major classes of soils (Table 2) used for interpreting crop potential. In fact, this approach itself is the concept of soil series yielding

information on productivity, in particular to the traditional use of soils as well as their quality, which is reported to be closely related to the development of risk minimization strategies along with slope, water, and pastoral resource management.^[8]

THE PHYSICAL DIMENSION

The physical dimension, which is the primary approach in indigenous classification (as in all visual research systems), includes color and touch (feeling) in assessing soil texture—as the Yoruba people in Nigeria have rubbed soil between fingers to tell if they are sandy (Yanrin), clayey (Bole), loamy (Alaadun), or loamy clay (Bole and Alaadun).^[9,10] Moreover, texture was used by ancient Peruvians as basis to designate eight major soils, in the same way that bulk density was classified by weight and ease of penetration of the cutlass.^[9] Color and equally refined physical dimension of indigenous soil classification were used by the Baruya people of Wonenera, New Guinea, as a source of pigment consisting of nine different colors for ceremonies and six others for agricultural soils.^[11] As dark soils are considered more fertile than their lighter-colored counterparts the farmers of Niger have designated soils with different color classes in relation to land degradation as: 1) fertile black soils (labu biri) with high organic matter; 2) white soils (labu kware) with

Table 1 Indigenous soil classification and their equivalents in soil taxonomy and World Reference Base (WRB).

Local classification	Central concept	Soil order and soil name
Blatong pantad	Thick, dark-colored, well-structured surface horizon; high base saturation	Mollisols, Cambisols (rich in organic matter)
Kalibugan	Brown clayey soil; deep; subsurface clay horizon; high base saturation	Alfisols, Luvisol (brown forest soil)
Puro Pantad	Brown or reddish color; clayey; deep; low base saturation; have subsurface clay horizon	Ultisols, Acrisol, Nitisol (red mountain soils)
Pra ambao	Strongly weathered; reddish and yellow colored; low exchange capacity; lack of weatherable minerals; absence of clay illuviation; very low natural fertility	Oxisols, Ferralsols (strongly weathered soils)

Source: From Maglinao,^[7] USDA,^[12] and Lambert, Daroussin, et al.^[13]

plant nutrient depletion by cultivation and erosion; and 3) further-degraded red soils (labu kirey).^[14,15] Taste has been another major criterion to assess acidity and salinity among Malaysian and Thai farmers with the sweet, the neutral, and the sour relating to the Western concept of soil pH.^[16,17] The Lari people in Peru have been able to separate taxons for eatable soils. The high Tundra soils are

Table 2 The Mossi farmers' (Africa) indigenous soil classes.

Major classes	Zşkugri (stony soil)	Bşisri (sandy soil)	Bolle (clay soil)	Bşoogo (loamy soil)
Derived soils	Zşka (lateritic soil)	Bşs-miuugu (red sandy soil)	Dagre (hard clay soil)	Zş-bugri (very soft soil)
	Rasempuiiga (gravelly soil)	Bşs-sabille (black sandy soil)	Zş-sabille (black soil)	Zş-naare (wet loamy clay soil)
	Tşnga (mountainous soil)	Zş-peelee (white soil)	Zş-kotşka (a clay soil in a low land where water stagnates)	Kşongo (black soil with a dense growth of bushes as vegetal cover.
	Zş-miuugu (red soil)			

Source: From Dialla.^[3]

rich in minerals and salt and are eaten by the Laris as condiments or used as fatteners for animals.^[18]

THE PERCEPTUAL APPROACH

The perceptual approach of soil classification may include features other than the physical dimension, i.e., the utilitarian color–touch–texture domain stated by Posey^[19] and Weinstock.^[16] These features reflect the environmental priorities on soils based on their suitability, particularly for managing pastures or indigenous particular crops as in the case of Anatolian–Turkish land use context (Z.A. Savatlı, private communication, Adana Farmers Association, Adana, Turkey; Table 3).^[20]

Table 3 The Anatolian indigenous soil classification and their equivalents in WRB.

Local soil classification	LU context	Soil name WRB (2001)
Keli (fertile soils)	Sandy loam to loam, good drainage and irrigable lands of the Mediterranean region	Cambisols, Fluvisols
Dambası (fertile soils)	Loamy to sandy loam, very good drainage and irrigable lands of the Mediterranean region nearby villages	Cambisols, Fluvisols
Malaz	Deep clayey soils developed on marls in need of drainage and conservation management/tillage	Fluvisols, Cambisols
Dölek	Deep clayey soils of sedimentary origin in need of drainage and conservation management/tillage	Fluvisols, Cambisols
Kepir	Slightly sloping to flat land, i.e., calcrete terraces with shallow to moderately deep red to reddish brown soils suitable for agroforestry with indigenous tree crops (olives, carobs, figs, vineyards and stone pine)	Calcisols, Cambisols, Luvisols
Cökek	Water logged playas to be managed as wetlands	Vertisols, Fluvisols
Bozkır	Slightly degraded land with primary saline areas of Inner Anatolian grazelands	Cambisols, Calcisols
Dazkır	Degraded Bozkır soils of the mild aridic Inner Anatolian indigenous overgrazed pastures in need of management	Cambisols, Calcisols
Corak	Soils of Inner Anatolia with primary and secondary salinity suitable for halophyte and/or biodiversity	Fluvisols, Cambisols, Calcisols

Source: From Lambert, Daroussin, et al.^[13]

Similarly, the Melanesians of the Trobriand islands have classified soils for the suitability of yam or taro (their main diet) crops: dumya soil is good for dry season taro or, but not for yam; butuma soil is excellent for yam, but unsuitable for taro; malala soil is unsuitable for taro, but good for hardy yam; sawewo soil is good for large yam; galaluwa soil is good for all cultivation; and the very fertile kwala soil is good for all crops. (B. Malinowski, cited in Ettama.^[16]) Mixed cropping is also an extensive practice in indigenous societies, especially in the form of shifting cultivation, giving rise to soil classifications based on vegetation covers rather than on soil properties.^[21] Such biological indicators, i.e., vegetation and soil macrofauna, which actually reflect soil suitability, are also common to

Table 4 Indigenous use of biological indicators of soil quality: vegetation and macrofauna.

Vegetation	
Malaysia	<i>kedukuk</i> bush (<i>Melostoma</i>) indicates high Al level <i>Pohon bakan</i> (<i>Hanguana</i>) tree indicates acid soil with stagnant water <i>Imperata</i> grass, <i>keriang</i> berry bushes and cashew indicate low soil fertility
Shipibo, Peru	Use indicator plants for soil hydrology
Caatinga, Brazil	Thinly wooded vegetation indicates imperfect drainage
S. Mexico	Sparse vegetation is general indication for <i>tierra delgada</i> , thin soil
Maya, Mexico	Dark-colored vegetation high soil fertility
Kekchi, Guatemala	Use indicator plants for site suitability for <i>Milpa</i> agriculture
Mebengokre, Brazil	Use indicator plants for general site suitability
Gaborone, Botswana	Use indicator plants for soil fertility
Yoruba, Nigeria	<i>Odundun</i> (<i>Kalanchoe</i> sp.) indicates high soil fertility, while <i>Eran</i> (<i>Digitaria horizontalis</i>), <i>Okan</i> (<i>Combretum platypterum</i>), and <i>Pepe</i> (<i>Mallotus oppositifolius</i>) indicate poor fertility
Niger	Dark, dry roots of millet seedlings indicate 'sick' soil which is not fertile
Soil Fauna	
Yoruba, Nigeria	Earthworm casts indicate fertile soil
Sukuma, Tanzania	Termite soil is fertile, soil classification based on their presence/absence
Niger, Sierra Leone	Soil close to ant and termite hills is fertile and planted with special crops
Ecuador	Earthworm casts and grub casts (?) indicate good soil
Thailand	Soil from termite hills is used as soil fertility improver

Source: From Ettama.^[15]

non-shifting cultivation in many parts of the world (Table 4).^[15] These indigenous societies employ specific types of crops to determine the level of soil fertility, drainage characteristics, and acidity.

CONCLUSION

Indigenous soil classification systems may generally seem to be more shallow when compared to contemporary classifications.^[9,11,21] Indigenous soil classifications primarily bear a functionality for land use, whereas common contemporary classification systems divide soils mainly based on knowledge on pedogenesis.^[21,22] Second, indigenous soil taxa are derived from surface horizon properties, while the diagnostic features of differentiation of contemporary soil taxa are the character and sequence of soil horizons, i.e., the perception of taxonomic units is 2-D in indigenous classification and 3-D in the contemporary. Further studies undertaken by Bellon and Taylor^[23] revealed that soil quality-wise ranking by indigenous perception and scientific method gave similar results, showing that the distinctions made by local people were all scientifically valid and statistically testable.

Classification Systems: Major

Lars Krogh

Geographical Institute, University of Copenhagen, Copenhagen, Denmark

Abstract

Numerous systems have been developed and exist for the classification of soils and soil materials, serving a variety of purposes. As international references, however, the agriculturally biased, morpho-genetic systems, Soil Taxonomy and World Reference Base, for soil resources have gained widespread acceptance. With increasing demands on small-scale quantitative soil information and a reality where soil information must be able to address a broad range of environmental issues other than agricultural production, the soil research community is faced with a major challenge in meeting this demand and thinking along new lines to develop new soil information systems.

INTRODUCTION

Soil classification is a tool for stratifying, generalizing, remembering, predicting, mapping, and communicating information on soil resources for a specific purpose and, in addition, it serves as a basis for further enquiry into soil processes.

Soil cover varies continuously vertically and horizontally at many scales in response to the interactive effects of climate, vegetation, relief, parent material, time, and the human activities. Soils have many users and the use of soils also varies according to climate, technology, land cover, agricultural systems, trade possibilities, and traditions, and therefore the concepts of soils are very diverse. In addition, the very nature of soils—slowly evolving three-dimensional bodies with no distinct borders, and thus no true “individual” object for classification—in combination with the late “discovery” of soil science probably explains why numerous and diverse systems of soil classification have evolved over time: from the ancient Chinese and Egyptian tax assessment systems, to the scientific, national, and partly global systems of the Western world and to the advanced, geostatistical, fuzzy logic systems.

The American classification system *Soil Taxonomy*^[1] and the joint FAO, ISRIC, and ISSS system *World Reference Base (WRB) for Soil Resources*,^[2] which is a further development of the FAO–UNESCO *Soil Map of the World*^[3] and its update from 1988,^[4] are the two most widely accepted and used soil classification systems. In addition, the Australian,^[5,6] Brazilian,^[7] Canadian,^[8,9] Chinese,^[10] French,^[11] and Russian^[12–14] systems might also be considered major systems in that they are used on a large proportion of the land surface of the earth. However, these systems have all been developed for national purposes only.

SOIL TAXONOMY

Building upon available soil concepts and classification systems in the United States, the development of *Soil Taxonomy* was started in 1951 and through a series of modifying steps the *Seventh Approximation* was published in 1960^[15] followed by the publication of the definitive system for the first time in 1975, under the name *Soil Taxonomy*.^[16,17] The system has been amended nine times since then (published as keys) and is continuously undergoing modifications to encompass results of new research and changing soil concepts, and the second comprehensive edition was published in 1999.^[1,18] The original purpose of the system was to serve as a tool for making and interpreting soil surveys in the United States, predominantly in relation to agricultural production, but in years it has evolved into a means of communication in soil science. *Soil Taxonomy* differs from most other systems by its rather special names for describing soils, which were created to avoid older traditional names that have ambiguous meanings. At the time of publication, it was among the very few systems that separated soils on the basis of precise quantitative definitions of observable and measurable properties.

Soil Taxonomy is a hierarchical, six-level, morphogenetic classification system, in which soils can be arranged—with decreasing rank and with increasingly narrower variation in properties—in 12 orders, 64 suborders, about 300 great groups, about 2400 subgroups, about 8000 families, and (in the United States) about 20,000 series.

Soil Taxonomy has defined a number of diagnostic horizons (Table 1) and diagnostic soil characteristics, which are used to identify and assign soils into its categories by the means of a key. Diagnostic horizons are recognized as reflecting common and widespread results of major

Table 1 Brief description of the 8 diagnostic epipedons and the 20 diagnostic subsurface horizons in *Soil Taxonomy*

	Description
Epipedons	
Anthropic (Gr. <i>anthropos</i> , human being)	Manmade, thick, dark, formed by long continued residence or application of organic residues. Often with high phosphorus content
Folistic (L. <i>folia</i> , leaf)	More than 20 cm thick, high in organic matter of cool humid regions under forest vegetation
Histic (Gr. <i>histos</i> , tissue)	Between 20 and 40 cm thick, high in organic matter that is saturated with water for long periods
Melanic (Gr. <i>melas</i> , black)	Thick, black, high in organic matter of soils formed from volcanic ash. The organic matter is associated with short-range order minerals or Al-humus complexes
Mollic (L. <i>mollis</i> , soft)	Thick, dark, high in organic matter, well structured with over 50% base saturation, predominantly from divalent cations. Typical for steppe soils
Ochric (Gr. <i>ochros</i> , pale)	Thin, light, or low in organic matter, thereby failing to be mollic or umbric
Plaggen (Ger. <i>plaggen</i> , sod)	Manmade, more than 50 cm thick, high in organic matter, and raised above the original soil surface. Formed by spreading of a mixture of manure and sod, the latter used for bedding livestock in medieval times
Umbric (L. <i>umbra</i> , shade = dark)	Thick, dark, high in organic matter, well structured with under 50% base saturation
Subsurface horizons	
Agric (L. <i>ager</i> , field)	Illuvial horizon below the plow layer containing silt, clay, and organic matter. Formed under (old-world) cultivation
Albic (L. <i>albus</i> , white)	Eluvial, bleached and light-colored horizon from which clay and Fe-oxides have been removed
Argillic (L. <i>argilla</i> , white clay)	Horizon with significantly higher clay content than horizon above. Formed through clay illuviation and/or <i>in situ</i> weathering
Calcic (L. <i>calcis</i> , lime)	Illuvial horizon with secondary CaCO ₃ as powder or concretions. Mostly found in arid environments
Cambic (L. <i>cambiare</i> , to exchange)	Horizon in which weak structure formation, weathering of primary minerals, and precipitation of Fe-oxides have taken place
Duripan (L. <i>durus</i> , hard)	Horizon cemented by illuvial silica thereby impeding root and water movement
Fragipan (L. <i>fragilis</i> , brittle)	Compact, high bulk density, non-cemented horizon impeding root and water movement
Glossic (Gr. <i>glossa</i> , tongue)	Transitional horizon with vertical bleached tongues formed by movement and destruction of clay and Fe-oxides in existing argillic horizon
Gypsic (L. <i>gypsum</i> , gypsum)	Illuvial horizon with secondary gypsum. Mostly found in arid environments
Kandic (from kandite)	Horizon with significantly higher clay content than horizon above and dominated by LAC clays. Formed through clay illuviation and/or <i>in situ</i> weathering
Natric (L. <i>natrium</i> , sodium)	Horizon with significantly higher clay content than horizon above and 15% or more exchangeable Na. Formed through clay illuviation and/or <i>in situ</i> weathering
Ortstein (Ger.)	Cemented horizon consisting of complexes of Al and organic matter with or without Fe (spodic materials)
Oxic (F. <i>oxide</i>)	Fine textured, thoroughly weathered horizon with clay consisting of LAC and sesquioxides and having a low CEC. Mostly found in old tropical environments
Petrocalcic (Gr. <i>Petra</i> , rock and calcic)	Indurated illuvial horizon with secondary CaCO ₃ . Mostly found in arid environments. Barrier to roots and water
Petrogypsic (Gr. <i>petra</i> , rock and gypsic)	Indurated illuvial horizon with secondary gypsum. Mostly found in arid environments. Barrier to roots and water
Placic (Gr. <i>plax</i> , flat stone)	Thin (<25 mm), black to reddish horizon cemented by Fe (and Mn) and organic matter
Salic (L. <i>sal</i> , salt)	Horizon with accumulation of salts more soluble than gypsum and in quantities harmful to roots. Mostly found in arid environments
Sombric (F. <i>sombre</i> , dark)	Horizon with illuvial concentrations of organic matter that is not in combination with Al. Mostly found in cool, mountainous environments
Spodic (Gr. <i>spodos</i> , wood ash)	Illuvial horizon with amorphous material consisting of organic matter and Al with or without Fe
Sulfuric (L. <i>sulphur</i> , sulfur)	More than 15 cm thick mineral or organic horizon with low pH (pH = 3.5) formed by artificial drainage of sulfide rich materials

pedogenetic processes and are defined by observable and measurable morphological and chemical properties. Diagnostic horizons present at the surface are termed epipedons and those present below the surface are termed subsurface horizons. Diagnostic soil characteristics, some unique to mineral soils and some unique to both mineral and organic soil, are also defined by specific morphological and chemical properties. They do not, however, necessarily make up a coherent horizon, and they also include soil water and temperature characteristics as defined by several soil moisture and soil temperature regimes. For a soil to be assigned into a category at any level of the system, a soil must meet the criteria specified in the definitions of the category.

Soil orders are separated on the basis of stable and long-term development processes and properties reflected by diagnostic horizons (Table 2); suborders are separated on the basis of mostly dynamic properties controlling the soil-forming processes, such as soil moisture regime and the presence or absence of water or vegetation; great groups are separated on the basis of generally static properties with minor or additional control on soil-forming processes; subgroups are separated on the basis of a central concept and divergence from this; families are separated on the basis of properties that relate to plant growth or the potential for further change; series, which are the mapping unit carrying local names, are separated on the basis of properties that reflect relatively narrow ranges of soil-forming factors. To illustrate the special nomenclature of *Soil Taxonomy*, the name Typic Argiaquolls

(subgroup level) signifies that the soil is a typical base rich soil with a deep, organic matter-rich A-horizon (Mollisol) that is relatively wet (Aquic conditions) and with clay accumulation in the subsoil (argillic subsurface horizon).

THE WRB FOR SOIL RESOURCES

The *WRB for Soil Resources* was developed jointly by the ISSS, FAO, and ISRIC through a series of steps and published in 1998.^[2,19–21] It is not an entirely new system, but rather a revision of the FAO–UNESCO *Soil Map of the World* from 1974^[3] and the so-called FAO Revised Legend from 1988,^[4,22] to some extent, it is also inspired by *Soil Taxonomy* and the French *Référentiel Pédologique*.^[12] It was launched to provide scientific depth and background to the FAO system, as it became clear that important new insight and knowledge about the world's soils had been generated. Additional objectives are to serve as a link between national classification systems, to serve as a basic language in soil science, to strengthen the application of soil science, and to facilitate the use of soil data for other professionals in soil and land management. Together with the superseded FAO system, WRB is the only system specifically designed to accommodate global soil resources.

The WRB system is a two level morphogenetic system. At the highest level, it has 30 reference soil groups that represent the major soil regions of the world (Table 3).

Table 2 Brief description of the 12 orders in *Soil Taxonomy* and their surface area in percent.

Order	Formative name element and meaning	Brief description of order	Percentage of ice-free land surface ^a
Alfisols	Alf (M. ^b <i>Pedalfer</i>)	Weakly weathered soils with argillic or kandic horizon and high base saturation in subsoil	9.6
Andisols	And (Jap. <i>an</i> , dark)	Soils formed from volcanic ash and with short-range order minerals	0.7
Aridisols	Id (L. <i>aridus</i> , dry)	Weakly developed soils of dry regions	12.0
Entisols	Ent (M. <i>recent</i>)	Soils with very weak pedogenic development	16.2
Gelisols	El (L. <i>gelare</i> , to freeze)	Soils with perennial permafrost within 100 cm of the surface	8.6
Histosols	Ist (Gr. <i>histos</i> , tissue)	Periodically wet soils with more than 30% organic matter to a depth of 30 cm	1.2
Inceptisols	Ept (L. <i>inceptum</i> , beginning)	Soils with incipient development in terms of weathering, color, and structure	9.8
Mollisols	Oll (L. <i>mollis</i> , soft)	Soils with mollic horizon and high base saturation	6.9
Oxisols	Ox (F. <i>oxide</i> , oxide)	Highly weathered red soils of the tropics	7.5
Spodosols	Od (Gr. <i>spodos</i> , wood ash)	Acidic soils with spodic horizon	2.5
Ultisols	Ult (L. <i>ultimus</i> , last)	Strongly weathered soils with argillic or kandic horizon and low base saturation in subsoil	8.5
Vertisols	Ert (L. <i>vertere</i> , to turn)	Soils with more than 30% expandable clays in all horizons and development of cracks during dry periods	2.4

^aIce-free land surface = 129,788,231 km².

^bM = meaningless syllable.

Table 3 Brief description of the 30 reference soil groups in *WRB for Soil Resources* and their surface area in percent.

Reference soil group	Formative element	Brief description of reference soil groups	Percentage of ice-free land surface ^a
Histosols	Gr. <i>histos</i> , tissue	Periodically wet soils with more than 30% organic matter to a depth of 30 cm	2.2
Cryosols	Gr. <i>kraios</i> , cold ice	Soils with perennial permafrost	12.3
Anthrosols	Gr. <i>anthropos</i> , man	Soils transformed by human activity through deep working, application of plaggan manure, or sediment-rich irrigation water	?
Leptosols	Gr. <i>leptos</i> , thin	Weakly developed shallow soils with hard rock within 25 cm of surface	11.5
Vertisols	L. <i>vertere</i> , to turn	Soils with more than 30% expandable clays in all horizons and development of cracks during dry periods	2.3
Fluvisols	L. <i>fluvius</i> , river	Soils developed on stratified floodplain deposits	2.4
Solonchaks	Russ. <i>sol</i> , salt; <i>chak</i> , salty area	Soils with accumulation of soluble salts	2.1
Gleysols	Russ. <i>gley</i> , wet soil	Poorly drained waterlogged soils with mottles and anaerobic conditions	5.0
Andosols	Jap. <i>an</i> , dark; <i>do</i> , soil	Soils formed from volcanic ash and with short-range order minerals	0.8
Podzols	Russ. <i>pod</i> , under; <i>zola</i> , ash	Acidic soils with accumulation of amorphous material consisting of organic matter and Al with or without Fe in the subsoil (spodic horizon)	3.4
Plinthosols	Gr. <i>plinthos</i> , brick	Soils with mottled appearance because of segregation of iron oxides, which harden upon exposure to the air	0.4
Ferralsols	L. <i>ferrum</i> , iron; <i>alumen</i> , aluminum	Highly weathered red soils of the tropics with high content of Fe/Al oxides and LAC clays	5.2
Solonetz	Russ. <i>sol</i> , salt; <i>etz</i> , strongly	Soils with high content of exchangeable sodium	0.9
Planosols	L. <i>planos</i> , flat	Soils on flat terrain with abrupt textural change from sandy surface to clayey subsoil, which causes seasonal water stagnation	0.9
Chernozems	Russ. <i>chern</i> , black; <i>zemlja</i> , earth	Dark-colored loess soils of the grass steppe regions with high content of organic matter and accumulation of calcium carbonate in subsoil	1.6
Kastanozems	L. <i>kastanea</i> , chestnut; Russ. <i>zemlja</i> , earth	Brown-colored soils of the grass steppe regions with high content of organic matter and accumulation of calcium carbonate or gypsum in subsoil	3.2
Phaeozems	Gr. <i>phaios</i> , dusky; Russ. <i>zemlja</i> , earth	Dark-colored soils of the steppe regions with high content of organic matter and leaching of calcium carbonate	1.3
Gypsisols	L. <i>gypsum</i> , gypsum	Soils with accumulation of secondary gypsum	0.6
Durisols	L. <i>durus</i> , hard	Well-drained, arid region soils with compact and silica-cemented layer	?
Calcisols	L. <i>calx</i> , lime	Soils with accumulation of secondary calcium carbonate as soft powder or as cemented layers	5.6
Albeluviols	L. <i>albus</i> , white; <i>eluere</i> , to wash out	Soils with clay accumulation in subsoil penetrated by tongues of coarse-textured and lighter material of eluvial horizon	2.2
Alisols	L. <i>alumen</i> , alum	Acidic soils with clay accumulation in subsoil, high CEC, and low base saturation	0.7
Nitisols	L. <i>nitidus</i> , shiny	Low latitude, deep, well-drained soils with clay accumulation in subsoil and shiny ped-surfaces	1.4
Acrisols	L. <i>acer</i> , strong acid	Acidic, weathered soils with clay accumulation in subsoil, low CEC, and low base saturation	7.0
Luvisols	L. <i>luere</i> , to wash	Soils with clay accumulation in subsoil, high CEC, and high base saturation	4.5
Lixisols	L. <i>lixia</i> , washing	Strongly weathered soils with clay accumulation in subsoil, low CEC, and high base saturation	3.0
Umbrisols	(L. <i>umbra</i> , shade = dark	Well-drained soils with dark-colored, organic-rich, acidic surface horizon (umbric horizon)	0.7
Cambisols	L. <i>cambiare</i> , to change	Soils with incipient weathering and slight development of color and structure	10.5
Arenosols	Gr. <i>arena</i> , sand	Soils with sandy texture throughout	6.3
Regosols	Gr. <i>rhegos</i> , blanket	Weakly developed fine-textured soils	1.8

^aIce-free land surface = 129,788,231 km².

Table 4 Nearest WRB equivalents to the 12 orders in *Soil Taxonomy*.

Soil Taxonomy orders	WRB reference soil groups
Alfisol	Luvissols, Lixissols, Planossols, and Solonetz
Andisol	Andosols
Aridisol	Leptosols, Gypsisols, Durisols, Calcisols, Solonchaks
Entisol	Arenossols, Fluvisols, Regossols, and Gleysols
Gelisols	Cryosols
Histosols	Histosols
Inceptisol	Cambisols; Fluvisols, Gleysols, and Solonchaks
Mollisol	Chernozems, Kastanozems, Phaeozems
Oxisol	Ferralsols, Plintossols
Spodosol	Podzols
Ultisol	Alisols; Acrisols; and Albeluvisols and Nitisols
Vertisol	Vertisols

In Table 4, the nearest WRB equivalents to the 12 soil orders in *Soil Taxonomy* are shown.

At the second level, the WRB is a classification system where combinations of 121 qualifiers may be added to the reference groups, thus allowing very precise characterization of individual soil profiles. Traditional soil names have been retained to the greatest extent possible, e.g., Podzols and Solonetz, but in case of ambiguity of traditional names, new names derived from various linguistic roots were selected, e.g., Albeluvisols instead of Podzoluvisols.

For describing the reference soil groups, WRB has defined 40 diagnostic horizons, 12 diagnostic properties [assemblages of soil characteristics, e.g., texture, color, soil reaction, and cation exchange capacity (CEC)], and 7 diagnostic soil materials (original parent materials that are only slightly altered, e.g., anthropogenic material, fluvic material, or sulfidic material). Diagnostic horizons and properties are the expression of pedogenic processes and have been defined as representing generally agreed pathways of soil formation and importance for soil management and use. Many of the differentiating criteria have been adopted from *Soil Taxonomy* either directly and simplified, e.g., the mollic, umbric, and ochric horizons, or modified and simplified, e.g., the argic B horizon (from the argillic subsurface horizon) and the ferrallic B horizon (from the oxic subsurface horizon). In contrast to *Soil Taxonomy*, the use of soil climate is not part of the system, except for the effects it may have on soil properties. Assignment of soils into the WRB categories is by means of a key. To illustrate how second level classification systems of WRB work, a reddish-colored Vertisol with a surface-near calcic horizon would be termed a Chromic Vertisol.

CONCLUSION

Numerous systems have been developed and exist for classification of soils and soil materials, serving variety of purposes. As international references, however, the agriculturally biased, morpho-genetic systems, Soil Taxonomy and WRB, for soil resources have gained widespread acceptance. With increasing demands on small-scale quantitative soil information and a reality where soil information must be able to address a broad range of environmental issues other than agricultural production, the soil research community is faced with a major challenge in meeting this demand and thinking along new lines to develop new soil information systems.

Classification Systems: Netherlands

Alfred E. Hartemink

International Soil Reference and Information Centre (ISRIC), Wageningen, the Netherlands

Henk de Bakker

Netherlands Soil Survey Institute (StiBoKa), Wageningen, the Netherlands

Abstract

Although people have always classified soils, only since the mid-19th century has soil classification emerged as an important topic within soil science. It forced soil scientists to think systematically about soils and its genesis, and it was developed to facilitate communication between soil scientists. It has also been the cause for much debate and confusion, but two internationally accepted systems have emerged: Soil Taxonomy and the World Reference Base for Soil Resources (WRB). In addition, many national soil classification systems exist whose methods and approaches are based on one of the international soil classification systems or which have influenced these systems. In this entry, we describe the Dutch soil classification system, which was essentially developed after the fourth International Congress of Soil Science in Amsterdam in 1950.

INTRODUCTION

The Netherlands is a low-lying country with the lowest point at nearly 7 m below mean sea level just north of Rotterdam. The highest point is 321 m above mean sea level and located in the southern part of the country. About half of the country is below sea level and would be inundated without dikes and dunes. It is also a wet country, and more than 90% of the soils have groundwater within 140 cm of the soil surface during winter. As a result, most Dutch soils are hydromorphic and require artificial drainage when taken in use. There is no consolidated rock, and the parent material is alluvial (marine or fluvial), or aeolian, glacial, or organic. About one-third of the country consists of embanked forelands from either the North Sea or the rivers Scheldt, Rhine, and Meuse; these polders have Holocene loamy and mostly clayey soils. About 40% of the Dutch soils have Pleistocene sands as parent material and 2% loess. Peat areas comprise about 25% of the Netherlands.

BRIEF HISTORY OF SOIL MAPPING AND SOIL CLASSIFICATION

W.C.H. Staring (1808–1877) made the first geological map of the Netherlands at a scale 1:200,000 in the 1850s. At the request of a teacher's society, the map was simplified and used in education on basic schools for over a century. Until the 1940s, there was little activity in soil surveying, although much work was done in the Dutch East Indies by E.C.J. Mohr (1873–1970), and there was intensive and

detailed soil fertility research by D.J. Hissink (1874–1956) in Groningen.

The focus of Staring and his followers was on the topsoil, and relatively little was known about the whole solum, soil genesis, and geography. This changed in the 1930s when W.A.J. Oosting (1898–1942) started soil mapping around Wageningen. Inspired by the work of Oosting, C.H. Edelman (1903–1964) started soil surveying with his students in the riverine clay area during World War II. The Dutch Soil Survey Institute (StiBoKa) was founded by Edelman in 1945. Soil maps were very much in demand in areas with severe war damage such as, e.g., polders that were inundated with seawater, minefields, and for restoring airfields to agricultural use. His book *Soils of the Netherlands* was published on the occasion of the 1950 Congress of the International Society of Soil Science (ISSS) in Amsterdam.^[1] The accompanying map (scale 1:400,000) reflects the main Staring classes (i.e., sea clay, river clay, sand, loess, and peat), but for the subdivision physiographic criteria are used. The Edelman approach was strongly based on geology and the landscape, which resulted in the Dutch school of physiographic soil mapping. The fieldwork for the map at a scale 1:200,000 took place between 1952 and 1954, and it was published in 1960. In 1952, the Soil Survey Institute started to map the whole country at 1:50,000 (110 sheets), which was published between 1964 and 1995.^[2]

The physiographic approach for soil mapping was less suitable for soil classification, and the legends of the map provided more insight into geogenesis than into pedogenesis. In the 1950s and 1960s, soil classification was widely discussed because of an increasing number of soil scientists

working in soil mapping, increased international interaction following the Congress of ISSS in 1950, and the development of soil classification in the United States. Under the guidance of the main author of *Soil Taxonomy*, G.D. Smith, Dutch soil scientists discussed the series of approximations and a committee started to frame a system of soil classification using inherent soil properties as differentiating criteria rather than physiographic and geological criteria. It formed the base for the Dutch system of soil classification.^[3]

THE DUTCH SYSTEM OF SOIL CLASSIFICATION

At the highest level, soils are differentiated by soil-forming processes, and as such, the system has a profound pedogenic base. Units in the classification system are defined by morphometric properties and characteristics of the soil profile. There are five orders, and a brief description including the equivalents in *Soil Taxonomy* is listed in Table 1. A Podzol or textural B horizon and the formation of an A horizon are diagnostic criteria at the order level. In addition, the absence of soil formation or the presence of peat as parent material is used at the order level. No soil chemical criteria are used at the order level because of the heavy use of manure and inorganic fertilizer applications in the Netherlands.

The five orders are subdivided into 13 suborders, 23 groups, and 58 subgroups (Table 2). Criteria to distinguish the lower levels of classification include texture, organic

Table 1 The five orders and their diagnostic properties and equivalents in Soil Taxonomy and the WRB.

Orders	Main diagnostic property	Approximate equivalent in Soil Taxonomy	Approximate equivalent in the WRB
Peat soils	>40 cm peat within 80 cm depth	Histosols	Histosols
Podzol soils	Soils with Podzol B	Spodosols (aquods and orthods)	Podzols
Brick soils	Soils with a “brick” layer	Alfisols (hapludalfs)	Luvisols and Planosols
Earth soils	Soils with a mineral earthy layer	Mollisols, Inceptisols (aquic soils with a mollic or anthropic epipedon)	Anthrosols
Vague soils	Without foregoing diagnostic horizons	Entisols and Inceptisols	Fluvisols, Gleysols, Anthrosols, Regosols, Cambisols, and Arenosols

matter content, hydromorphic characteristics, peaty topsoil, plaggen epipedon, and ripening class. Processes such as gley formation, ripening, and the influence of cultivation are considered at the suborder level, and hydromorphic properties are profoundly present at the suborder level as in many other systems of soil classification. At the group level, differences in parent material are considered as are the presence of peat layers and the stage of ripening. At the lowest level (subgroup), topsoil properties are important. Although the subgroup level is the lowest level in the Dutch Soil Classification System, lower classification levels are used in the 1:50,000 soil map of the Netherlands. It is

interesting to note that the 1:50,000 soil map reflects Starling's main classes of the mid-1800s.^[4]

SOIL NOMENCLATURE

The highest categories (order, suborder, and group) have names adopted from the existing terminology, but in some cases, artificial terms are chosen. At the subgroup level, names have been chosen that are a combination of Dutch toponyms and the name of the order; e.g., “Aar” peat soils are found around the villages of Langeraar and Ter Aar in the province of South Holland, whereas most of the “koop” peat soils are names after villages ending in koop (e.g., Boskoop and Teckop). Some of the names stem from medieval reclamation (e.g., “rooi” from uprooting shrubs or trees). Other names are from rivers and lakes or low-lying areas (e.g., “tocht” and “daal”) or from the dominant type of land use (“weide” = pasture and “akker” = arable land).^[3] An overview on toponyms and soil nomenclature is given by Siderius and de Bakker.^[5]

CONCLUSIONS

The Dutch Soil Classification System was developed in the 1960s following decades of physiographic soil mapping. The system has a strong pedogenic base at the highest level, and parent material and hydromorphic properties are important. There are 5 orders, 13 suborders, 23 groups, and 58 subgroups. This system was used as the background of the legend for the 1:50,000 soil map published in 110 sheets between 1964 and 1995. Although the system stems from the 1980s and no attempts have been made to update or revise the system, it continues to provide useful information on the genesis and geography of soils in the Netherlands.

Classification Systems: Russian

Maria Gerasimova

Faculty of Geography, Moscow Lomonosov University, Moscow, Russia

Abstract

The first soil classification systems appeared in Russia on the eve of the 20th century, and the imprint of their ideology and conceptual priorities has remained very strong in the later systems. Both early Russian schemes developed by Dokuchaev and Sibirtsev are traditionally regarded as factor genetic, i.e., they comprise the notions on the origin of soils, soil-forming processes, and soil position in the system of geographical zones. However, some importance was attributed to soil properties, moisture and temperature regimes, and the stage of soil development. These major features of pedogenetic manifestations and environment have proved to be key points in the further development of the classification schemes in Russia. Subsequent schemes differed in the priorities given either to the environment (zones) or to soil genesis or to soil properties.

BACKGROUND INFORMATION

The diversity of approaches to soil classification was always inherent to Russian pedology. Unlike the early and existing American systems, all Russian schemes started from “above”: the lowest taxa were derived from the upper ones, the names of which were retained in the low-category soil name; in other words, there was no similar concept to that of the American Series in the Russian approach. The majority of systems were hierarchical, with the soil type being the central unit. The definition of the soil type serves to illustrate the fundamental principles underlying the classification (Table 1). During the development of the various classification systems, different sets of criteria for the upper taxonomic levels were proposed: soil genesis in terms of soil-forming processes, or soil age; soil chemical and/or morphological properties; soil horizons; and soil-forming agents. The categories higher in the system than soil type differed in definition depending upon the conceptual approach of the author(s), while the below-type categories have remained basically unchanged since they were first specified in the late 1950s. Not all classification systems have distinguished categories at levels higher than soil type.

The “discovery” of soil science by Dokuchaev^[1] resulted in a simple and descriptive zonal soil classification system, which was the *first* in Russia. It was presented as a table with short comments in 1886. All soils—14 groups were subdivided into normal—*zonal* soils, *transitional* (boggy-meadow soils, Rendzinas, and Solonchets), and *abnormal* ones (e.g., alluvial and eolian). Groups of zonal soils were ascribed to zones and characterized in terms of processes, sediments, climate, vegetation, fauna, and topography. The system of Sibirtsev^[2] was slightly more advanced; the soils known in those times were grouped into *zonal*, *intrazonal*, *incomplete*, and *surface*

geologic formations, and lower categories were outlined as related to soil texture and parent rocks.

The ecological–genetic system of Gerasimov et al.,^[3] under supervision of Prassolov, is widely recognized to be based on the strictly defined notion of “genetic soil type,” with subdivision related to the potential drainage and/or position in a catena. Soil sequences were identified as automorphic, hydromorphic, and semihydromorphic. The definition involves processes of substance migration–accumulation–transformation, geographic environments, soil evolution, and pedogenetic processes, which are specifically emphasized. A first categorization of subtypes and species was proposed; species—stages of pedogenetic process development—were later transformed into quantitative groupings. Units of the lowest category were identified in relation to land use and soil degradation (old-arable limed, old-irrigated, secondary saline, etc.).

In 1956, Ivanova^[4] published a classification for world soils, which was widely criticized by foreign and some Russian soil scientists because of its over reliance upon climatic subdivisions. Indeed, the highest taxa were differentiated with respect to climate and vegetation, the names of soil types were supplemented with landscape characteristics (e.g., red soils of dry savanna). The degree of soil hydromorphism (automorphic, transitional, and hydromorphic series) was also taken into account at the higher (above-type) level. Given this complexity, it is perhaps not surprising that the number of genetic soil types reached 80. The system was termed evolutionary genetic–geographical and highly appreciated in the USSR for its geographical essence.

Two more classification systems illustrate the diversity of concepts that have prevailed in the former USSR. Both were concerned with the above-type categories, and they have common approaches to the choice of soil properties serving as differentiating criteria.

Table 1 Scheme of taxonomic units in some classification systems in USSR/Russia.

	Author(s) (year)					
	Dokuchaev ^[1]	Gerasimov et al. ^[3]	Official systems (1967, 1977)	Kovda et al. ^[5]	Glazovskaya ^[6]	New system ^[10]
Criteria for the upper level	Zonality	No upper level		Soil age, budget of substances	Eh, pH, weathering, humus type	Pedogenesis vs. lithogenesis
(Genetic) soil type						
Criteria for lower levels	Subtype	Catenary and plants effects	Additional process	Not discussed		Diagnostic features
	Genus	—	Parent material			CEC, type of salinity
	Species	Stages	Quantitative characteristics			
	Variety	Texture				
	Phase	Human impacts	Degree of erosion	Not discussed		Parent material

^aOnly two levels were presented in this pioneer system, both related to zonality.

Perception of soils as results of broad geochemical mass–energy exchange processes interacting in time parallel to the evolution of landscapes served as background for the world system elaborated by Kovda et al.^[5] The upper category is represented by broad soil geochemical formations differentiated by major trends of weathering and clay minerals, types of humus, acid–base properties, supplemented with characteristics of climate and vegetation. For example: “Formation of acid, strongly freezing or cryogenic soils. Weak weathering. Clay of illite–hydromica type. Main processes: humus and peat accumulation, weak podzolization, gley, cryogenesis. Taiga vegetation. Cold boreal climate” (1975). The second entry—stadial groups of soils—corresponded to hypothetical evolution stages from submerged sites to excessively drained ones. The following stadal groups were proposed: hydroaccumulative, hydromorphic, mesohydromorphic, paleohydromorphic, proterohydromorphic, automorphic (including mountain soils), and paleoautomorphic. The number of stadal groups and of soil geochemical formations varied in different versions of this system; moreover, climatic zones or belts were sometimes introduced, and climatic facies appeared in the final version. The latter was published as the legend of the World Soil Map, scale 1:10 M, 1975. The system was severely criticized for a high degree of clumsiness, insufficient paleogeographical substantiations, and internal inconsistency.

A similar geochemical approach was implemented by Glazovskaya^[6] in the classification of world soils in late 1960s. Most of her genetic–taxonomic ideas were applied in the legend of the World Soil Map (produced for higher level educational use at universities, colleges, and advanced secondary schools) at a scale of 1:15 M, in 1981. This system is strictly hierarchical: there are three above-type levels: associations, generations (classes), and families. Soil types are arranged in families in accordance with distinct rules. Lower categories were preserved as traditional. Criteria for differentiation at the highest category are pH

and soil features indicative of redox conditions; members of the second category are differentiated by a range of process-related properties, including broad processes of organic matter accumulation, formation of secondary minerals, translocation of substances, and effects of groundwater. The difference in the composition of pedogenetic accumulations (humus, illuvial horizons, concretions, etc.) allows the specification of families within classes that were the main soil units on the world map.

Official systems—an initial approximation produced in 1967 and the final version of 1977(a) derived from the system of Ivanova of 1956. Both systems lacked any above-type categories, whereas the lower ones were clearly and adequately defined. The 1977 version is best known in Russia and abroad. It was translated into English (1986) and has been efficiently used in soil survey and small-scale mapping since then. The ecological–genetic principle of the system was applied practically for all hierarchical categories and soil diagnostics. The upper category corresponds to genetic soil types, of which there are more than 100. The subtypes are very large, both conceptually and in number. Many subtypes were required to cover many and diverse soil features owing to their dual nature: there are subzonal and facies subtypes, both variants being more geographic than taxonomic units. The concept of subzonal subtypes as “central images” of types and intergrades corresponding to subzones did not contradict the traditional interpretation of subtypes as modifications of types by superimposed processes, while the facies subtypes are really virtual phenomena. They were recognized only by climatic parameters (total air and topsoil temperatures > 10°C, depth and duration of soil freezing), and their names were like this: “very cold deeply (freezing to a depth in excess of 1 m) and long freezing ...”

The third—genus—category contained much information on parent rocks, groundwater, and soil history, and its differentiating criteria were far from being universal for different types. Species (or kinds in some translations) and

subspecies, unlike genera, were more consistent in specifying the quantitative parameters of pedogenetic processes (not horizon's properties!). For example, the thickness of humus-accumulative horizon and humus content in the 0–10 cm layer served to qualify the intensity of the “chernozemic process.” Texture characteristics and erosion phases were also accommodated in this system.
